All this would, I think, involve a whole-time salaried service, and although there were very sound arguments against this before July 5, 1948, we have now been jockeyed into a position where we can lose nothing by it, and where many benefits would result to ourselves, the public, and the Treasury. Certainly nothing could be worse than the financial and medical chaos that is going on in general practice at present, and I would prophesy that in the not too distant future the profession itself will beg for a salaried service.

This letter merely contains a number of disjointed and disputable points which require an elaboration beyond the bounds of your correspondence columns, but unless some such revolutionary changes are made the general practitioner will continue to suffer the frustration of a man educated above his job and its prospects, and the National Health Service will suffer the fate of a house built on sand.—I am, etc.,

Selkirk. E. H. DUFF.

Bifocal Glasses

SIR,—I do not understand the reason for the recent Ministry embargo on a patient's having two pairs of glasses at once (*Supplement*, September 3, p. 125), the rule now being that he gets his near-sight glasses in about seven months' time and his

distance ones in about 18 months. There is absolutely no need for anyone to have two pairs of glasses, bifocal ones in the same frame being much better. If the patient goes out with his distance glasses on, in a great many cases when he or she wants to see something—e.g., in a shop—close to, he finds that he has left his near-sight glasses at home on the mantelpiece or has lost them. Without glasses I can see nothing either near or far properly, but some years ago I got fitted with a bifocal pair, and since then have been able to see everything, both near and far, perfectly.

When I write "Bifocal necessary" on the green O.S.C.1 forms I supply to patients I find that in nine cases out of ten the ophthalmic surgeon or optician has turned me down and has told the patient that he needs two pairs of glasses, with the accompanying intolerable delay. As the only G.P. member of our local ophthalmic committee I asked the reason for this, and the answer given by one of the opticians present was, "Pure laziness." Apart from the inexcusable slackness so freely admitted by a member of the ophthalmic fraternity, surely it would be cheaper to have two lenses in one frame than to have two separate pairs of glasses.—I am, etc.,

Stowmarket, Suffolk. H. S. GASKELL.

Pay of Hospital Staff

SIR,—In the issue of September 3 there is an advertisement for an R.M.O. (B1) at the Devon and Exeter Hospital. It states that a senior medical qualification and experience will be required. Does the Devon and Exeter Hospital intend to pay an able man with several years' experience and a higher qualification as a junior registrar? Are all the Spens recommendations now in the wastepaper basket, put there by our own profession? When Mr. Bevan himself has stated that he intended to abide by the spirit of Spens, we find our own profession failing to do so.

No doubt you have good reasons for publishing this advertisement, but it does seem surprising, especially in view of your firm attitude towards cut-price advertisements for assistant M.Os.H. Hospital jobs are difficult enough to get nowadays. Let the successful men be paid a salary in accord with their qualifications and the work they are expected to do.

The fact that the administrative members of the medical profession are grading and paying hospital men far below the scales formerly agreed upon could surely be used as evidence that men in other fields of medicine are being overpaid. Mr. Bevan might justifiably apply the axe all round, merely stating that he was following the example set by our own profession.

While we realize that the assessing committees would not allow this outburst to influence their attitude to our appeals now under consideration, we have accepted the advice of senior colleagues, and sign ourselves

SIX BEWILDERED.

Squatter's Comments

SIR,—The Medical Practices Committee's report (*Supplement*, September 10, p. 128) and the *Practitioner's* review of the Health Service contain material of great interest and importance to general medical practice. But when I correlate my own experiences as a squatter with the truths, half-truths, and discrepancies of these two publications I have a sense of despair and frustration. All we ask is a chance to examine and treat patients and to claim a reasonable living.

It is generally accepted that the best way to enter general practice now is as an assistant. It is the best way because it is the only easy way. But it puts the young and not so young doctor at the mercy of the established practitioner.

The review suggests that the local committees should be given more power to regulate practice in their own areas. The Medical Practices Committee, according to their report, would scarcely agree with that. It is not local knowledge alone that must be considered, but local peculation. If my own local committees had had their way I should not have been able to practise here. As it is I have managed to scrape up a panel of about 1,500 in less than 12 months. That is not much on which to rear five children, but it is a beginning, considering the delay and opposition which I experienced.

The fact seems to be that we cannot expect members of our own profession in positions of authority to behave without prejudice when their own decisions may affect their own incomes, as must be the case with the present system of remuneration. The present attempt at regulated commercialism is not a safe resting-place between complete freedom on the one hand and a full-time salaried service on the other. If the influential members of our own profession continue to act in this way we shall soon be "ripe for the plucking." There will arise sufficient hardship and sufficient unemployment within the profession to enable a Government to bring in a full-time salaried service.—I am, etc.,

L.

Higher Pay without Parades

SIR,—In your issue of September 3 appears an advertisement requesting applications from surgeons, gynaecologists, and E.N.T. specialists to serve with the R.A.M.C. overseas in a civilian capacity. An F.R.C.S. is offered a salary of £1,700 per annum, plus accommodation and other allowances, for a period of up to two years.

Had the same man, in a more patriotic mood, accepted a commission in the R.A.M.C. eight years ago and attained the rank of major and the same qualification he would now be earning a salary (as a bachelor) of £784 15s. plus £73 qualification pay, together with similar allowances and a right to a pension after a further 12 years' service.

It is therefore theoretically possible, in fact probable, that a civilian surgeon could be working side by side with an R.A.M.C. specialist and be drawing twice the pay of the latter without having to attend parades, etc. Such an offer, seen from within the Service, can only increase one's resentment at the delay in bringing specialists' pay into line with that in the National Health Service. Until this is done I consider that such advertisements should not be accepted for publication in the *B.M.J.*—I am, etc.,

MAJOR, R.A.M.C.

Representation of Hospital Medical Staffs

SIR,—In your report (*Supplement*, October 1, p. 151) of the last meeting of the Central Consultants and Specialists Committee you omitted to mention the most important of its decisions.

It was decided, without reference to the regional committees, to agree to the proposal of the Joint Committee that the Joint Committee would appoint and instruct the members of the staff side of the Whitley Council which the Government had announced its intention of setting up shortly. In effect, this decision means that the Central Consultants and Specialists Committee has finally subordinated itself and surrendered the power it was given, when it was constituted by the A.R.M. of 1947, to the Joint Committee, a body which for the most part is not elected even indirectly by or can be fully in touch with the working hospital medical staffs of the country. This in itself is contrary to the meaning of a Whitley Council, which is a committee composed of representatives of the employed staff on the one side and of the employers on the other. As once the medical Whitley Council is set up it will be the Standing Committee for the settlement of disputes or alterations of the terms of service, it will be essential to hospital medical staffs to be able to appoint and instruct directly the members of the staff side of the council. They will not be able to do so through the Joint Committee, over which they will have no control except through the minority of its members derived from the Central Consultants and Specialists Committee.

It was understood when the Consultants and Specialists Committee of the B.M.A. was reconstituted that the object was to provide democratic representation of consultant opinion from the whole country. This appears to have been negatived by the latest action of the Central Consultants and Specialists Committee on a question of major policy, as indeed it was last year, by the setting up of the Joint Committee.

The South-West Metropolitan (Western Area) Regional Committee has, from the first, disagreed on this ground with the formation of the Joint Committee. However, it considers that there may have been some justification for the existence of the Joint Committee during the past year to act as a Liaison Committee between the Colleges and the B.M.A. while the general terms and conditions of service for hospital staffs have been under discussion. But in its view there is now no need or justification for this undemocratic condition to continue. It has noted that the move to form the Joint Committee was made even before the Central Committee had first met, and that the representation of the Central on the Joint Committee was fixed at a small minority.

It has been noted also that the Joint Committee has omitted to report regularly its proceedings to the Central Committee and finally acted without authority in agreeing with the Ministry to recommend the terms for the permanent contracts for hospital staffs, while discarding almost all the points of objection or modification which had been previously put forward by the Regional and Central Committees. Such behaviour does not inspire confidence in the Joint Committee for the future conduct by it of the affairs of hospital staffs, even if the staffs were prepared to waive their right to democratic representation.

The South-West Metropolitan (Western Area) Committee considers that interest in the B.M.A. organization for hospital medical staffs is not likely to be maintained if the Central Committee continues to surrender its power. The lessening attendance at central and local meetings is already an indication of this.

Our committee has decided unanimously that if the Central Consultants and Specialists Committee continues to be subordinated to a Joint Committee it will consider withdrawing its representatives from the Central Committee and relying on representation of its members by other means. The other regional committees of the B.M.A. organization have been informed of this decision.—We are, etc.,

Freedom Preferred

SIR,—I have read with dismay—indeed with some disgust—Dr. Conn McCluskey's letter (*Supplement*, October 1, p. 157). Surely he is one of an extremely small minority in desiring to be "directed . . . what to do and when to do it," or possibly he has cast himself in the role of a director and not one to be directed.

His statement that "there seems to be little tyranny in the artisans' trade unions" is very far from the truth. Has he not heard of men being debarred from a particular employment because they did not belong to a particular trade union? Has he not heard of restrictions of effort and output being imposed by trade unions upon their members?

He thinks that a "democratically elected body" cannot implement a tyranny. History is full of evidence to the contrary; or, if historical evidence does not seem relevant to him, then all contemporary politics will furnish him with abundant examples to confute his statement.

A state of tyranny must inevitably arise when a tyrannically disposed individual or group of individuals acquires power over a community whose members prefer the security of serfdom to the perils of freedom. In that unenviable predicament I believe the medical profession now to be. I trust we shall not reverse Aesop's fable and add King Log to King Stork by forming a trade union which would be—I hope—as impotent as it would be degrading. The only foreseeable advantage in such an action would be to have attained a point in the spiritual evolution of our profession where we could truly say, "He that is low need fear no fall."—I am, etc.,

Stafford. JOHN FREW.

BRITISH MEDICAL STUDENTS ASSOCIATION

The seventh Annual General Meeting of the British Medical Students Association will be held at B.M.A. House, Edinburgh, on November 11–13. The guest lecture will be given by Mr. P. Eggleton, D.Sc., reader in biochemistry at the University of Edinburgh, on November 11, at 2.30 p.m. Anyone interested is invited to attend this lecture.

Representatives from most medical schools in the country will be attending to discuss such matters as student health services, clinical conferences, staff–student discussions, further-education and training grants, and medical films, as well as routine domestic matters.

B.M.A. LIBRARY

The following books have been added to the Library:

Advances in Surgery. Volume 1. 1949.
American Association of Physical Anthropologists: Studies in Physical Anthropology. No. 1, Early Man in the Far East. 1949.
Atomic Energy Year Book: Edited by John Tutin. 1949.

H.M. Forces Appointments

ROYAL NAVY

Surgeon Commander S. J. Savage has been placed on the Retired List.

Surgeon Lieutenant R. R. B. Baxendine to be Surgeon Lieutenant-Commander.

ROYAL NAVAL VOLUNTEER RESERVE

Surgeon Lieutenant-Commander E. J. S. Woolley, O.B.E., has been placed on the Retired List.

Surgeon Lieutenants W. E. A. Buchanan, A. C. MacDonald, J. F. McHarg, and R. A. McKeown to be Surgeon Lieutenant-Commanders.

ARMY

Colonel R. S. Dickie, late R.A.M.C., having attained the age for retirement, is retained on the Active List supernumerary to Establishment.

Lieutenant-Colonel J. N. Atkinson, late R.A.M.C., to be Colonel.

ROYAL ARMY MEDICAL CORPS

Lieutenant-Colonel P. E. D. Pank has retired on retired pay, and has been granted the honorary rank of Colonel.

Major D. S. Cochran to be Lieutenant-Colonel.

Major W. N. S. Donaldson, T.D., from Short Service Commission, to be Major.

Captains T. B. Harrison, O. S. Williams, and J. F. Webb, M.C., to be Majors.

Captain C. C. Petrovsky has retired, receiving a gratuity, and has been granted the honorary rank of Major.

Short Service Commission (Specialist).—Captain (War Substantive Major) I. F. Fraser has retired, receiving a gratuity, and has been granted the honorary rank of Major.

Short Service Commission.—Captains J. E. G. Earle and J. M. Corall have retired, receiving a gratuity, and have been granted the honorary rank of Lieutenant-Colonel. Captains I. A. Jackson, M.B.E., and A. J. Leslie-Spinks to be Majors. Captains W. G. Canning and J. P. X. Fox have retired, receiving a gratuity, and have been granted the honorary rank of Major.

REGULAR ARMY RESERVE OF OFFICERS

ROYAL ARMY MEDICAL CORPS

Lieutenant-Colonel (Honorary Colonel) C. B. C. Anderson, O.B.E., having attained the age limit of liability to recall, has ceased to belong to the Reserve of Officers.

Captain B. E. Schlesinger, O.B.E., from Supplementary Reserve of Officers, to be Major, and has been granted the honorary rank of Colonel.

Captains J. P. Stewart, F. A. D'Abreu, R. G. M. Longridge, N. M. L. Lund, J. C. Harland, and G. Macpherson, from Supplementary Reserve of Officers, to be Majors, and have been granted the honorary rank of Lieutenant-Colonel.

Captains D. C. Muir, A. C. F. Green, H. J. Browne, J. H. Chambers, F. G. Wood-Smith, D. P. Kearns, R. Cox, M.B.E., T. J. Fairbank, W. M. Macleod, P. H. Newman, D.S.O., I. N. Samuel, G. C. Steel, F. R. Store, I. H. Griffiths, E. H. C. Harper, G. Lorriman, M.B.E., R. R. Simpson, and A. W. F. Catto, from Supplementary Reserve of Officers, to be Majors.

Captain R. A. Strang, from Emergency Commission, to be Captain, and has been granted the honorary rank of Major.

TERRITORIAL ARMY

ROYAL ARMY MEDICAL CORPS

Lieutenant-Colonel (Honorary Colonel) Sir Hugh W. B. Cairns, K.B.E., has been appointed Honorary Colonel.

Colonels C. P. Oliver, C.B., C.M.G., T.D., and W. D. Watson, T.D., have relinquished their appointments as Honorary Colonels, their tenure of appointment having expired.

Captain (*acting* Lieutenant-Colonel) G. E. Parker, D.S.O., has been granted the acting rank of Colonel.

Major G. K. D. Edwards has been granted the acting rank of Colonel.

Captains (Acting Majors) M. F. Ronayne, M.B.E., J. G. Waugh, T. P. Sewell, and J. Bleakley to be Majors.

Captains J. Davidson, T. M. Lennox, M. A. Watson, I. R. McNeish, and C. J. Cobbe, M.B.E., to be Majors.

Association Notices

GROUP COMMITTEE ELECTIONS

As a result of elections held recently among the Special Groups, the following have been elected to the various Group Committees. Re-elected members are indicated by an asterisk, and, subject to the amendments shown below, the full list of members of the Committee is as set out in the *Supplement* of August 20 (p. 90).

Anaesthetists Group

Provinces: *Z. Mennell.
*W. W. Mushin.
Scotland: A. C. Forrester (*vice* H. H. Pinkerton).

Consulting Pathologists Group

*J. G. Greenfield.
R. Cruickshank, W. H. McMenemey } *vice* A. F. S. Sladden and F. B. Smith.

Dermatologists Group

London: D. I. Williams (*vice* L. Forman).
Provinces: *F. F. Hellier.
Scotland: *J. Ferguson Smith.

Orthopaedic Group

London: *P. Wiles.
Provinces: *S. A. S. Malkin.
Scotland: R. Barnes (*vice* A. Miller).

Physical Medicine Group

*F. S. C. Cooksey.
*J. W. T. Patterson.
One vacancy (*vice* J. B. Burt).

Psychological Medicine Group

*P. K. McCowan.
*J. R. Rees.
T. Ferguson Rodger (*vice* A. A. W. Petrie).

Radiologists Group

*J. F. Brailsford.
*S. Whately Davidson.
*J. L. A. Grout.

Spa Practitioners Group

North: T. G. Reah (*vice* L. J. Prosser).
South: J. E. Dawson.

Venereologists Group

R. C. L. Batchelor.
R. Lees.
A. E. W. McLachlan.
C. Hamilton Wilkie.

PRIZES FOR MEDICAL STUDENTS, 1950

The Council of the British Medical Association is prepared to consider the award in 1950 of prizes to medical students for essays submitted in open competition.

The subject of the essays shall be "Clinical Teaching in Relation to the Practice of Medicine."

The purpose of these prizes is the promotion of systematic observation among medical students. In awarding the prizes due regard will be given to evidence of personal observation. No study or essay that has previously appeared in the medical

press or elsewhere will be considered eligible for a prize. Any medical student who is a registered member of a medical school in Great Britain or Northern Ireland at the time of submission of the essay is eligible to compete for a prize.

If any question arises in reference as to the eligibility of a candidate or the admissibility of his or her essay, the decision of the Council of the British Medical Association shall be final. In determining the number and the value of the prizes to be awarded the Council will take into consideration the number of essays received. Should the Council decide that no essay entered is of sufficient merit, no awards will be made.

Each essay must be typewritten or legibly written in the English language, on one side of the paper only, must be unsigned, and must be accompanied by a form of application which can be obtained from the undersigned. Essays must be forwarded so as to reach the Secretary of the British Medical Association not later than December 31, 1949. Inquiries relative to the prizes should be addressed to the Secretary, British Medical Association, B.M.A. House, Tavistock Square, London, W.C.1.

SCHOLARSHIPS IN AID OF SCIENTIFIC RESEARCH

The Council of the British Medical Association is prepared to receive applications for Research Scholarships as follows: An Ernest Hart Memorial Scholarship of the value of £200 per annum, a Walter Dixon Scholarship of the value of £200 per annum, and four Research Scholarships each of the value of £150 per annum. These scholarships are given to candidates whom the Science Committee of the Association recommends as qualified to undertake research in any subject (including State medicine) relating to the causation, prevention, or treatment of disease. Preference will be given, other things being equal, to members of the medical profession.

Each scholarship is tenable for one year starting on October 1, 1950. The scholar may be reappointed for not more than two additional terms. A scholar is not necessarily required to devote the whole of his or her time to the work of research but may hold an appointment at a university, medical school, or hospital, provided the duties of such an appointment do not interfere with his or her work as a scholar.

Conditions of Award: Applications

Applications for scholarships must be made not later than Friday, April 28, 1950, on the prescribed form to be obtained from the Secretary of the Association, B.M.A. House, Tavistock Square, London, W.C.1. Applicants will be required to furnish the names of three referees who are competent to speak of their capacity for the research contemplated.

CHARLES HILL,
Secretary.

Diary of Central Meetings

OCTOBER

21	Fri.	Committee *re* Capital Punishment, 2 p.m.
25	Tues.	Anaesthetists Group Committee, 2 p.m.
25	Tues.	Central Ethical Committee, 2 p.m.
26	Wed.	Joint Subcommittee *re* Remuneration of National Coal Board M.O.s (Conference of Colliery Medical Officers), 2 p.m.
26	Wed.	Spa Practitioners Group Committee, 2 p.m.
27	Thurs.	Annual Conference of Representatives of Local Medical Committees, 10 a.m.
28	Fri.	Library Subcommittee, 11.30 a.m.
28	Fri.	Consulting Pathologists Group Committee, 2 p.m.
28	Fri.	Science Committee, 2 p.m.
31	Mon.	Armed Forces Committee, 2 p.m.

NOVEMBER

2	Wed.	(At Lion Hotel, Shrewsbury) Welsh Committee, 2.15 p.m.
3	Thurs.	Committee on Industrial Health Services in relation to the National Health Service, 2 p.m.
9	Wed.	Committee on the Postgraduate Education of General Practitioners, 11 a.m.
10	Thurs.	General Medical Services Committee, 11 a.m.

Branch and Division Meetings to be Held

BOURNEMOUTH DIVISION.—At Grand Hotel, Fir Vale Road, Bournemouth, Friday, October 28, 7.30 p.m., annual dinner.

CAMBRIDGE AND HUNTINGDON BRANCH.—At Lecture Theatre, Addenbrooke's Hospital, Cambridge, Sunday, October 30, 3.15 p.m. Address by Dr. Robert Forbes: "Legal Hazards in Medical Practice." A discussion will follow.

KENSINGTON AND HAMMERSMITH DIVISION.—At St. Mary Abbots Hospital, Marloes Road, London, W., Tuesday, October 25, 8.30 p.m., clinical lecture. Mr. J. H. Carver: "Male Sterility"; Mr. V. B. Green-Armytage: "Female Sterility." A general discussion will follow.

OXFORD DIVISION.—At Horton General Hospital, Banbury, Wednesday, October 26, 5 p.m., clinical meeting. 7.15 p.m., dinner at Whateley Hall Hotel, Banbury (price 6s. 6d.).

WEST MIDDLESEX DIVISION.—At Nelson Room, Town Hall, Ealing, Friday, October 28, 8.30 p.m., Mr. Angus Maude: "The Conservative Attitude Towards the Health Scheme." Wives are invited.

WEST SUSSEX DIVISION.—At Warne's Hotel, Worthing, Tuesday, October 25, 6 p.m. Business meeting, followed by an address by Dr. Charles Hill on "Problems of the Moment"; 7.15 p.m., dinner (10s., including tip), followed by a discussion. All medical practitioners in West Sussex are invited to attend.

Meetings of Branches and Divisions

LEEDS DIVISION

The newly qualified medical graduates of Leeds University were invited to lunch by the Executive Committee of the Leeds Division on Thursday, September 29.

MASHONALAND BRANCH

The annual report of the Mashonaland Branch Council includes the following statement on State medicine: At the beginning of 1948 the Minister of Internal Affairs met separately both Branches of the British Medical Association in Southern Rhodesia. The verbatim report of the meeting in Salisbury was circulated to all members of the Branch and was discussed at a subsequent meeting. It has been only too obvious to all concerned that the Minister's proposals have not been acceptable to either Branch for the reason that the medical profession does not agree that such proposals will result in any improvement in the health services rendered to the population of Southern Rhodesia, European and African.

In the past there was not only a shortage of hospital beds, nursing staff, and medical equipment, but of medical practitioners as well. This last shortage has been remedied by private enterprise. The Government has failed to remedy the remaining lack, and, because of the Government's policy of providing hospital accommodation at an uneconomic rate to all, no private nursing-homes have been erected, and there is also no adequate private general or midwifery nursing service. The latter might have been remedied if a hostel had been built in which private nurses could live. However, in spite of this lack of private midwives, the Minister proposed to embark on a maternity service designed to encourage women to be delivered in their own homes. It is a matter of opinion whether it is better for a confinement to take place in a hospital or in the home, but without sufficient midwives the answer is obvious.

The Mashonaland Branch has felt in the past that, if the Government is determined to introduce a State medical scheme, the only efficient service would be one controlled by a Commission on which the medical profession is adequately represented. If the medical profession should form part of a Civil Service the Treasury would have the final say, and necessary schemes would not be carried out for lack of funds. The system whereby sums voted this year if not spent cannot be carried forward is iniquitous and leads to money being spent unnecessarily in times of plenty and for essential services to be curtailed in times of poverty. A sinking fund controlled by the Commission would remedy this. The Government's concern should in the first place be with the poorest, and it is feared that any so-called free national health service may result in less money being spent on the poorest and most numerous section of the community—the Africans. At present the medical vote for European and African health services is not divided.

To-day Southern Rhodesia is materially ill-equipped to supply a health service for the community. Given the tools, the private practitioners will render a service to the public more efficiently and at less cost than any other scheme, and if it should be said that the financial burden of ill-health cannot be borne by the individual we can rightly point out that a considerable proportion of the population can be members of medical aid societies, and that it should not be a difficult matter for the Government to provide medical aid in the form of a subsidized medical aid society for those of limited means who could not be members of one of the present societies.

METROPOLITAN COUNTIES BRANCH

Members of the Metropolitan Counties Branch, accompanied by their president, Dr. C. G. Martin, visited the Port of London on September 21 as guests of the Port of London Authority. The party was received by Admiral Sir Allan Hotham, member of the authority, and embarked in the P.L.A. s.y. *St. Katharine* at Tower Pier for a cruise down the River Thames and through the Royal Victoria and Albert and King George V Docks.

INDIVIDUALITY IN MEDICINE

HARVEIAN ORATION DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS ON OCTOBER 18, 1949

BY

GEOFFREY MARSHALL, M.D.Lond., F.R.C.P.

Consulting Physician to Guy's Hospital; Physician to Brompton Hospital for Diseases of the Chest

My Lord President and Fellows,

I have to thank you for the great honour which is mine in being entrusted with the delivery of the annual Oration, the two hundred and thirtieth to be given since the series was instituted by William Harvey's gift to the College in 1656. As you know, he directed that the Oration should be made in Latin, and should include a commemoration of all the Benefactors of the said College by name. With the passage of nearly three hundred years, good and practical reasons have been found for disobeying the strict letter of the terms of the Gift. I should add little to the dignity of this College if I attempted to address you in Latin, and I should like to pay tribute to the magnanimity of Dr. Alexander Sutherland, who, while giving the Oration in Latin in 1863, suggested that his successors might be allowed to address the College in English.

Benefactors

It is no longer the custom to commemorate all the Benefactors of the College by name and to record particulars of their benefactions, for the honourable reason that the list has become too long. I have pleasure, however, in recording a very recent benefaction, most appropriate to be commemorated in this Address. It is that of Dr. Ernest Christison Carter, who, being the senior member of this College, has presented the sum of one thousand pounds "to the end that friendship between members of the College may be continued and maintained, for the entertainment of distinguished guests from other countries, and if the Treasurer laid down some Port, that the health of the Senior Member should be drunk at one of the College Dinners."

William Harvey

Harvey bids us to search and study out the secrets of Nature by way of experiment; and also, for the honour of the profession, to continue in mutual love and affection among ourselves.

In these things Harvey was the great exemplar. When he was appointed Lumleian lecturer on anatomy in this College in 1615, there had been no notable advance in medicine for a thousand years. For political reasons the subject was confined within the orderly system formulated by Galen, and study consisted largely of disputation on the applications of this authoritarian creed. Unorthodoxy was punished by the civil power, as is happening now in a great territory governed by a union of republics.

A sidelight on Harvey's independence of mind and preference for personal observation is afforded by his discussion of the escape of the chick from the egg. First he quotes Hippocrates and his own teacher Fabricius of Padua. The latter had written:

"The chick wants air sooner than food, for it has still some store of nourishment within it; in which case the chick by his chirping gives a sign to his mother of the necessity of breaking the shell, which he himself cannot accomplish by reason of the hardness of the shell and the softness of his beak. The chick, nevertheless, is already so strong, and the cavity in the egg so ample, and the air contained within it so abundant, that the breathing becomes free and the creature can emit the sounds that are proper to it. These can be readily heard by a bystander, and were recognized by both Pliny and Aristotle, and perchance have something of a petition in their tone. For the hen, hearing the chirping of the chick within . . . she breaks the shell. The chirping of the chick is consequently the first and principal indication of the creature desiring to make its escape and of its requiring air. This the hen perceives so nicely, that if she hears the chirping to be low and internal, she straightway turns the egg over with her feet, that she may break the shell at the place whence the voice proceeds without detriment to the chick."

Harvey comments, "All this is stated pleasantly and well by Fabricius: but there is nothing of solid reason in the tale. I have found by experience that it is the chick himself and not the hen that breaks open the shell. I have further seen the chick raise up the top of the shell upon his head and remove it." So Harvey demolished an ancient fallacy by the simple method of observation; but he did it with gentle urbanity, a quality which we find in the exposition of his great discovery of the circulation of the blood. He deprecates harsh criticism of opponents in a field in which, as he says, "all have laboured well." His courtesy to opponents and his good humour were proof against many provocations. Physician to King Charles I, he received friendship and aid in his researches from his royal patient. While attending the King at Nottingham on the outbreak of the Civil War Harvey's lodgings in London were entered by a mob of citizen-soldiers. He writes:

"This is the cause of my sorrow: Whilst in attendance on the King during our late troubles and more than civil wars, not only with the permission but by the command of Parliament, certain rapacious hands not only stripped my house of all its furniture, but what is a subject of far greater regret to me, my enemies abstracted from my museum the fruits of many years of toil. Whence it has come to pass that many observations,

particularly on the generation of insects, have perished with detriment, I venture to say, to the republic of letters."

His exclamation does not seem over-emphatic: "Let gentle minds forgive me, if recalling the irreparable injuries I have suffered, I here give vent to a sigh."

At the end of the Civil War Harvey returned to London and we know that he attended meetings of this College. Here he must have encountered Fellows who had taken a prominent part with the Parliamentary Forces, and it is surely to his credit and to that of the College as a whole that no record of discourtesies or ill-natured repercussions can be discovered. Should we perhaps give special heed to this dignified tradition in a time of social change? Fortunately there is now no deadly civil war, but rapid changes in the relation of the individual to the State are not accomplished without injustice and resentment.

In 1654 Harvey was unanimously elected President of this College, an honour which he modestly declined. He had held the Lumleian lectureship for forty-one years, and seems to have discharged its duties with as much regularity as the times and his travels would allow. We hear of no complaints by the authorities of the College, but his absences caused uneasiness to some of his colleagues at St. Bartholomew's. He had been appointed physician to that hospital in 1609, and at a meeting of the Court of the hospital held on Sunday, January 19, 1633, inquiry was made into "a complaint of some of the chirurgeons of this hospital that whereas Doctor Harvey physician for the poor of the said hospital by reason of his attendance on the King's Majesty cannot so constantly be present with the poor as heretofore he hath been; but sometimes doth appoint his deputy for the same." The difficulty was resolved, and the Governors of the Hospital seem to have treated Harvey with consideration and respect.

In 1628 was published his book on *The Motion of the Heart and Blood*, which liberated medicine from the Dark Ages and set it on the path of progress which it has travelled ever since. The incontrovertible evidence with which he supports the validity of his discovery is based partly on anatomical dissection, partly on experiments on living animals, and partly on clinical observation. With regard to the latter, he quotes many illustrative cases of circulatory disease met with among his private patients and among the sick poor whom he attended at St. Bartholomew's Hospital.

British Hospitals

Let us review briefly the provision of hospitals in this country before and since Harvey's time. While medicine was dominated by the Church, under the Saxons and Normans, many hospitals were founded; we have written records of over eight hundred, and the majority of them survived to Tudor times. In 1534, Henry VIII broke with the Pope and soon set about the suppression of the religious houses. A statute of 1545 alleges that "governors and wardens of hospitals, or the greatest number of them, did not exercise due authority and expend the revenues in alms according to the foundation." The object of the Act was "to bring them into a more decent and convenient order." At the same time assurance was given that the King would not suffer "poor and miserable people to be unrelieved." Political propaganda is no new thing. Poor and miserable people did go unrelieved, for the hospitals were closed and deserted. Pressure by the citizens of London led in due course to the reopening of St. Bartholomew's and St. Thomas's, but these seem to have been the only two hospitals in London in Harvey's time, apart from St. Mary's of Bethlehem for the insane. In other parts of the country there were only a few vestiges of the old foundations. No renascence of hospital establishment occurred until the eighteenth century, but then the movement grew and flourished. In quick succession came the Westminster, Guy's, St. George's, the London, the Royal Infirmary in Edinburgh, and similar institutions in all the larger cities. By the end of the eighteenth century some forty important hospitals had been established, and in recent years the number of voluntary hospitals exceeded nine hundred.

These hospitals were not of equal size or merit. They were diverse in tradition, function, and administration. They were born and grew according to the need and the enterprise of the community, but they had certain features in common. They were modelled on the ancient foundations which had so well stood the test of centuries. They were governed by a group of laymen, usually men and women of proved ability and integrity, known and respected for their achievements in their own walks of life. They worked without fee or reward. In partnership with them was a medical staff, visiting or honorary, who received a token or peppercorn stipend, sufficient perhaps to pay their travelling expenses between home and hospital. The medical staff were responsible for the investigation and treatment of the patients allotted to them, and every member of this visiting staff was a member of the medical committee of the hospital. This committee advised the lay governors on all matters within their competence, and the governors referred to them all questions having a direct bearing on the medical and surgical work of the hospital. To quote from Harvey's great contemporary, Shakespeare, "I tell you that which you yourselves do know," and I hope that I shall not outwear your patience.

Appointments to the staff of the hospital were made by the governors, but in fact they depended on election by their colleagues acting in concert, of recent years with the help of external referees or assessors. I know of no other method so free of fear or favour, or which has given rise to fewer wrong decisions. The medical committees have advised the governors, in particular, concerning improvements in hospital equipment and accommodation required to make available to the patients the advances in medical science. It has been a point of honour with the medical committees to refrain from unreasonable demands, and it has been the constant endeavour of the lay governors to keep their hospital in the highest state of efficiency. Many of them have set an inspiring example of unselfish service, and out of this has grown a living corporate spirit in the voluntary hospitals. Their independence of central authority gave them individual character, vitality, and adaptability. They were institutions in which men and women were proud to work for no proportionate financial reward.

The service given by the voluntary hospitals to the public and to humanity in general has been no mean contribution. For many years in co-operation with the general practitioners they undertook the care of the poor in most cases of acute illness and severe injury.

In association with the universities they have been responsible for medical education. At first the students' fees went to the physicians and surgeons who taught in the wards and theatres, and the rewards were very high indeed by our standards. On the organization of medical schools, the clinicians gave up the major part, and in some hospitals the whole, of their teaching fees in order to finance the building, equipment, and staffing of the departments for preclinical teaching.

The increasing demand for hospital service, and its continuous elaboration, may be traced more or less directly

to Harvey's awakening of medicine from its long sleep. As a combined clinician and investigator he had worthy successors. Sydenham's work on fevers opened men's minds to the conception of specific infections. John Hunter established the principles of research in physiology and surgery. Edward Jenner laid the foundation-stone of immunology: a statue in Boulogne records his landing there to introduce vaccination into France at a time when our two countries were at war. Addison demonstrated the nature of pernicious anaemia, and with his description of the effects of disease of the suprarenals was a pioneer in the study of the ductless glands. Accurate knowledge of kidney disease dates from Bright. Anaesthesia was made practicable by Simpson, and all the great advances of surgery stem from Lister. Patrick Manson is known as the father of tropical medicine. Similar advances continue in our own time: those of Mott in mental disease, Mackenzie and Lewis in diseases of the heart, Gowland Hopkins and the Mellanbys in vitamins, Fleming and Florey in antibiotics. Medicine is not national and cannot flourish when confined; but we have a right to be proud of our share in fundamental discoveries, and most, if not all, of these workers were products of our voluntary hospitals.

Increasing elaboration of the methods of investigation and treatment necessitated the establishment of special departments, and at the same time attracted increasing numbers of patients to the hospitals, so that the visiting staffs had to cope with a vast free consulting service, which grew more rapidly after the passage of the Insurance Act. The cost in new building and equipment was heavy, but the hospitals expanded to meet the new requirements, drawing aid from the King's Fund and from contributory schemes.

Florence Nightingale

No individual has done more for the improvement of our hospitals and for the efficient and humane practice of medicine and surgery than Florence Nightingale. Her establishment of a training institute for nurses at St. Thomas's Hospital in 1859 led to the setting up of similar schools in all the large hospitals of this country. We may be thankful that we work under conditions revolutionized by her vision and determination. The nurses, doubly inspired by their foundress and by the corporate tradition of the various institutions in which they worked, raised our hospitals to a new excellence. Sir Henry Burdett, author of that standard work *Hospitals and Asylums of the World*, and originator of King Edward's Hospital Fund, did not hesitate to criticize those of our hospitals which he found inefficient. Influenced, perhaps, by his memories of Florence Nightingale's exposures of "officialism" in her reformation of the military hospitals in the Crimea, he wrote:

> "Anything more opposed to the best interests of the people than the substitution of State hospitals for the voluntary hospitals as they at present exist cannot be imagined. . . . We believe and hope therefore that the day is far distant when any serious effort will be made to substitute State hospitals for the noble medical charities which are at one and the same time the wonder of foreigners and the just glory and pride of the British nation."

Burdett was writing in 1900, a time made distant by great changes in the history of nations.

Florence Nightingale accomplished other reforms besides the reorganization of hospitals in the Crimea and the widespread establishment of training schools for nurses. Illness now confined her to bed for the rest of her life, but she kept in touch with many of the nurses who had been trained in her institute at St. Thomas's. One of them wrote to her from the Workhouse Infirmary at Liverpool and described the conditions in which the patients wore the same shirts for seven weeks and bedclothes were not washed for months. Such information as this she used to persuade the authorities to draft the Act of 1867 which separated the Poor Law infirmaries from the workhouse and provided them with resident medical superintendents. This was not all she wanted, and she said, "This is a beginning; we shall get more in time." In 1929 these institutions became the responsibility of the county and county borough authorities, since when many of them have attained a very high standard.

The Impact of War

In the recent war the voluntary hospitals were integrated with those of the local authorities, and a friendly partnership was in most cases established. They were placed under an Emergency Medical Service, and had an instructive experience of centralized control in an attenuated form. They learned something of its benefits and drawbacks, and minimized the latter by their traditional adaptability, especially in misinterpreting regulations and instructions which would have prevented efficient and humane treatment of their patients.

The hospitals in London were instructed to lock their gates when aerial bombardment was heavy, in order to prevent the breaking in of panic-stricken mobs. To the best of my knowledge only one hospital was mobbed. When heavy bombs struck the main block and destroyed both lift shafts and staircases a message was shouted from street to street that "Guy's is afire," and the men of Bermondsey and Southwark came out of their cellars and shelters in their hundreds and helped to carry the patients down the outside of the stricken building.

There was a great discrepancy in the efficiency of the hospital services provided by the different county authorities. Some were admirable and others miserably incompetent. Their responsibilities and obligations were heavy: one of the most troublesome was the provision of adequate and efficient institutional accommodation for those suffering from pulmonary tuberculosis.

In the good areas a patient urgently requiring admission would be taken into hospital within twenty-four hours, and the average period of waiting for a sanatorium vacancy for less acute cases did not exceed four weeks. On the outbreak of war a large proportion of the beds in tuberculosis institutions were emptied for the service of war casualties. A central administration which had failed to prepare for war thus repeated the mistakes of 1914. The premature return of infectious patients to their homes was followed by a steep rise in the tuberculosis rate, and there was a spectacular increase in child deaths from tuberculous meningitis. The hospital service for tuberculosis has not yet recovered from the disorganization resulting from this expropriation. Five thousand of its beds are still closed for want of staff. Patients in urgent need of treatment must wait from six to twelve months for admission to sanatoria or even to hospitals. Patients are lying in their homes begging for the treatment which can only be given in hospital, and which cannot be obtained until it is too late. Is there a Tudor echo in the recent assurance that the patients shall not suffer?

Ministry of Health

The Ministry of Health dates from 1919, and already has a distinguished record in preventive medicine. In the recent war it administered the Emergency Medical Service and so undertook responsibility for the treatment of

patients in many different types of hospitals. Experience so gained suggested the advisability of perpetuating the control, especially as it was said that the increasing cost of hospital maintenance and the heavy taxation of those who had heretofore financed the voluntary hospitals would make it impossible for them to survive on a voluntary basis. Lord Dawson's scheme for reorganization of the medical services, published in 1920, was revived and transfigured in the Beveridge Report. When the latter was published, it seemed to some of us that insufficient attention had been paid to the essentials which stimulate individuals and institutions to strive for progress in the science and practice of our calling. By memorandum and by word of mouth we reminded a former Minister of Health of the work of Florence Nightingale. We even suggested that this plan might undo some of the work that she had done, and that nurses might not care to work under such a scheme. We received no more encouragement than we expected. Others explained to us that Government money would be used, and that he who pays the piper calls the tune. This seemed to us an over-simplification : if each individual had his own piper he might get the tune he desired. In this case we are all paying the piper. Under a central authority there are millions who pay, and there is only one piper, remote in his office. Many of us call for different tunes. The piper has not the music for all the tunes, and some of them are unfamiliar to him. In the end, the piper is apt to play the tune which comes most easily to him, the one that suits his pipe.

State Hospitals

Our hospitals are now State hospitals : let us see to it that the change is not so disastrous as Sir Henry Burdett feared. We have inherited a splendid tradition from our great predecessors. Tradition grows like a tree, gathering strength by degrees ; but even a mighty tree can be cut down in a few hours. The tradition of the teaching hospitals is being respected ; they are being allowed to keep their constitution and character. They still have boards of governors ; but there is cause for regret that some of the most outstanding members of these boards, individuals of special distinction in the recent history of the voluntary hospitals, should have been superseded in the general reorganization.

Some of the other hospitals seem to be faring less well. Fifty thousand beds are out of service, largely, we are told, for lack of trained nurses. Some of the smaller voluntary hospitals have been closed. The character of others is undergoing a change. A recent official communication informs us that a hospital for pulmonary disease some sixty miles from London will no longer include consulting physicians on its staff. We are given to understand that, though their visits might be desirable, they cannot be fitted into the administrative pattern set by an Act of Parliament. We hear rumours of plans to standardize the design and limit the variety of instruments and chemical preparations used in the treatment of patients.

There are bound to be difficulties at the inception of a new service, and it is easy to criticize. We are here to help and not to hinder, but we shall do less than our duty if we fail to call attention in good time to inadvertences which tend to destroy the will of the individual to serve the community. The progress of medicine and the development of our hospitals have resulted from freedom and diversity, not from standardization and conformity.

With due humility let us ask that administrative departments of Government when taking over the control of our hospitals shall themselves absorb something of the spirit and tradition which has made them live and grow. Those who serve the sick cannot give of their best unless they possess the sense of urgency and personal responsibility. If Government control is to be beneficial to the hospitals there must be a new spirit in the ministries. There seems a need for more effective co-ordination between Government departments, and a stronger determination to avoid enmeshing themselves and us in a web of regulations and restraints. We would urge them to consider whether a multiplicity of committees may not be a hindrance to those who are striving to heal the sick.

I have strayed far from the course indicated by Harvey for the guidance of those who were to deliver the Oration, so make amends by reminding you again of his exhortation that we should search and study out the secrets of Nature by way of experiment ; and also, for the honour of the profession, continue in mutual love and affection among ourselves.

I. P. PAVLOV*

BY

J. KONORSKI, M.D.

Head of the Department of Neurophysiology, Nencki Institute of Experimental Biology, Lodz, Poland

It is both a great privilege and a great pleasure to take part in the centenary commemoration of the outstanding Russian physiologist Ivan Petrovich Pavlov. It is also a privilege to revive the memory of my work with this great scientist—work which, though now belonging to the past, I always recall with great affection.

I shall try first to survey briefly Pavlov's work and its significance for modern science, and then to give personal reminiscences of my association with him. I shall not deal here with the first phase of his work, which was devoted to the physiology of digestion and which alone was already sufficient to establish his permanent reputation, but with the second phase, in which he created a new branch of physiology—namely, the physiology of higher nervous activity.

To begin with, take a look at the study of physiology of the central nervous system at the stage it had reached by the turn of the century—that is, at the time when Pavlov was beginning his work. The rapid development of neurophysiology in the second half of the nineteenth century, achieved by physiologists and clinical workers such as Flourens, Hitzig and Fritsch, Ferrier, Goltz, Sherrington, Hughlings Jackson, Broca—to mention only the most outstanding ones—led to the establishment beyond doubt of the fact that mental processes depend on the function of the brain, more particularly of its highest and most complex part, the cerebral cortex. This does not mean that this fact had not been recognized earlier, but the research carried out by the scientists I have mentioned developed it in a direct and, so to speak, tangible manner.

On the one hand, the experiments of Hitzig and Fritsch, Ferrier, and others demonstrated that certain mental processes are localized to certain parts of the brain—a finding

*Lecture delivered on August 29, 1949, at the Polish Cultural Institute, London, on the occasion of the commemoration of the centenary of Pavlov's birth.

which was corroborated by clinical observation. On the other hand, the experiments of Flourens and Goltz indicated that after the removal of the cerebral cortex animals remained alive and in good health, but became, it was said, "soulless automata," "creatures without memory and mind." It must be remembered, moreover, that this work was going on in the full tide of nineteenth-century scientific materialism, when the theory of evolution on the one hand and the rapid progress of biochemistry on the other made it seem as though nothing could now impede the triumphant march of science towards the unravelling of all mysteries—even that of life itself. This, then, is the background of the events here reviewed.

It was becoming clear at the time that all our conscious activity and behaviour is controlled by the brain, and as such could be investigated, theoretically at least, by physiological methods, without reference to psychic phenomena.

This idea was already beginning to take hold on a very big scale. It was first clearly formulated by the prominent nineteenth-century Russian physiologist Sechenov in his booklet *The Reflexes of the Brain*. It is not surprising, therefore, to find that at the end of the nineteenth and the beginning of the twentieth centuries widespread attempts were being made to find an experimental approach to the problem in question. Of all the attempts then made two were developed further than any others and became part of the permanent structure of modern science. One line of inquiry was opened up in America at the end of the nineteenth century by Thorndike and later developed into that branch of psychology now known as "behaviourism." The other began several years later in Pavlov's physiological laboratory and gave rise to the physiology of higher nervous activity.

Although both these lines of investigation are concerned with one and the same field—namely, the objective approach to the study of animal behaviour—and although they now tend more and more to converge and coalesce, their origins and points of departure were widely different.

Thorndike, aiming at the objective investigation of animal behaviour, rejected introspective explanations. He was not concerned with the problem of what the animal "thought" or "felt" in its activities, but concentrated on trying to discover the laws governing its response to external conditions and stimuli. But, although he was not concerned with the subjective analysis of mental processes, he was nevertheless a psychologist, not a physiologist. Consequently, the physiological explanations he gave from time to time to supplement his arguments, though ingenious and penetrating, were somewhat amateurish. They neither were an integral part of his system nor were they later developed or elaborated.

With Pavlov it was a quite different matter. He was a physiologist through and through. His approach to cerebral activity was purely physiological, and he came to its study from what might appear to be a remote field—the physiology of digestion. It cannot be too strongly emphasized that both his aims and his methods were strictly physiological. Consequently, whereas the behaviourists, who in their investigations discounted mental processes as a link between external stimuli and reaction, had nothing to offer in place of these processes, Pavlov deliberately substituted physiological mechanisms for psychic activity.

Aim of His Work

The aim of Pavlov's work was not so much the description and classification of the phenomena of animal behaviour—the aim, more or less, of the behaviourists—as the explanation of those phenomena with reference to the relevant cerebral processes.

We must now look more closely at the starting-point and sources of Pavlov's work. In contradistinction to Thorndike, Pavlov worked solely on the basis of the physiological data then available. To him the fact that conscious behaviour of the organism depends on the cerebral cortex and therefore can be investigated as an expression of its functions admitted of no doubt. The problem consisted solely in how these investigations could be carried out. It was perfectly clear to Pavlov that experiments in the extirpation of certain cortical areas or in the stimulation of the cortex by electric shock—which were then widely practised—however fruitful and important they might be, did not represent the true method of investigating the normal and, so to speak, everyday activity of this organ. The problem was to find an appropriate method and the best starting-point for studying its *normal* activity.

While the work of Sechenov provided Pavlov with the theoretical basis, the practical method had already been formulated in Pavlov's earlier work. In the course of examining the activity of the salivary glands he had come across the phenomenon of so-called "psychological salivation." This occurs when the animal salivates, not in response to the actual presence of food or other stimulants in the mouth, but in response to the sight of food or to the sound of food being prepared—in other words, to the "idea" of food.

Pavlov saw that this simple fact offered a basis for the study of normal cortical activity. For if salivation in response to the presence of food in the mouth is an innate reflex, or, as Pavlov called it, "an unconditioned reflex," so salivation in response to the sight of food or the other stimuli signalizing its imminent presentation may also be regarded as a reflex action—not innate, but acquired through the animal's experience. This is what Pavlov called a "conditioned" or "conditional reflex."

The unconditioned reflex occurs by way of existing nerve channels established in the phylogenetic development of the nervous system, and is mediated mainly by the lower parts of the nervous system. The conditioned reflex, on the other hand, operates as the result of intercentral connexions established during the individual animal's lifetime as a result of its experience—connexions which depend, according to experimental evidence, chiefly on the cerebral cortex.

Pavlov argued that if the first of these reflex actions can be studied successfully by physiological methods—and no one can question the validity of these methods for the purpose—there can be no reason to doubt the validity of the physiological method for the study of the second group—that is, the conditioned reflexes.

It is thus apparent that the cerebral cortex (along with some subcortical structures), in contradistinction to the lower parts of the nervous system, may be regarded as a creative organ, a place where new connexions, and consequently new forms of animal behaviour, are established. This is its biological role and the essence of its physiological function.

And so we might sum up Pavlov's chief merit in this first period of his work on conditioned reflexes in the following way: it consists not in the fact that he understood the possibility of a physiological approach to problems of behaviour, for that possibility was well understood at the time and resulted from the general state of knowledge in the biological sciences; his great merit lay in bringing to

realization what hitherto had existed only in the realm of possibility—a *method* whereby cortical activity might be effectively and fruitfully examined.

Here it should be stressed that the method he then worked out for investigating conditioned reflexes in salivation may still be considered classical; for, although many other methods have since been added, his own has never been challenged for precision and scope.

It would be impossible, perhaps even inexpedient, to attempt to give an account, even in general outlines, of the work done by Pavlov's school during its 40 years' activity. But I should like to touch on some general questions closely related to this branch of science, particularly those which have given rise to some misunderstanding.

Reaction to His Work

Almost from the very beginning of the development of the study of higher nervous activity there sprang up a vast literature devoted to criticism, positive and negative, of the subject—criticism of a philosophical rather than a physiological character. This criticism was concerned with such questions as the validity of these investigations, their scope, their general philosophical significance, and so on. This critical literature is perhaps no less extensive than the literature of the subject itself, and often tends to overshadow the question at issue. Indeed, it frequently happens that a purely factual lecture or communication on the study of conditioned reflexes is at once made the pretext for a discussion which has nothing whatsoever to do with the real subject of the lecture but is devoted to such questions as the relation of mind to body, materialism, idealism, and so on, until amidst all these issues the proper subject is completely lost.

And so some people fulminate against the physiology of higher nervous activity, asserting either that it denies the existence of mind, that it attempts to explain mechanistically all our conscious activity, or that it over-simplifies the highly complex and subtle phenomena of mental life and tries to force them into the narrow framework of "reflexes," which these critics dismiss as elementary and primitive nervous functions. Others, on the contrary, extol the physiological method to the skies, dismiss with contempt years of psychological achievements, and maintain that psychology is not a science at all and that physiology alone is capable of giving a complete and adequate explanation of all our mental activity.

For some people the so-called intrusion of physiology into a field regarded as the preserve of psychology amounts to nothing less than sacrilege against the dignity of the human spirit. Others, on the contrary, consider the possibility of a physiological and objective approach to our conscious behaviour as the crowning achievement of the human spirit and its ultimate triumph.

Physiology of Higher Nervous Activity

For these reasons it may be useful if we try to clear away some at least of the confusion surrounding these questions and to define what the physiology of higher nervous activity is—and what it is not.

First we must realize that the subject we are dealing with is a branch of the biological sciences and, particularly, a part of neurophysiology. It is an experimental science which, on the basis of the observation of certain physiological phenomena, attempts to draw conclusions regarding their physiological mechanism. It would be no more reasonable to doubt the validity of these conclusions than to doubt, for instance, the validity of the findings concerning the structure of chemical compounds arrived at by chemical experiments.

That, of course, does not rule out the possibility that our present assumptions concerning the cortical functions may prove erroneous and that we may have to revise them more or less in the light of subsequent knowledge. For it must be remembered that this study of the most complicated arrangement of organisms, the brain, is one of the utmost difficulty, and therefore, in Pavlov's phrase, "when you aim so high it is no disgrace to fail." In fact, it is certain that in the development of this science many of our concepts will be proved wrong and will have to be replaced. All such changes, however, must occur in the fire of experiment, on the basis of strictly relevant factual evidence, and certainly not as the result of barren and purely speculative disputes such as I have already described.

But while the direct evidence of the science of conditioned reflexes and the laws formulated on the basis of that evidence cannot be at the mercy of general philosophical disputations—though they can and must be liable to constant and the closest scientific scrutiny—the general question of the application of these laws to various phenomena of animal, including human, behaviour is another matter altogether.

The problem under consideration may be expressed in this way: whether the laws discovered in experiments on conditioned reflexes in animals can be applied to human cortical activity and whether even now all cortical activity can be explained in physiological terms, or whether those laws are, as yet, applicable only to the most elementary cortical phenomena and their extension to the whole field of higher nervous activity is at present impossible.

Pavlov's standpoint was not unequivocal. On the one hand, endowed as he was with a highly critical mind, he realized that his work was only the beginning of the physiological analysis of cortical activity, and that, as he put it "the mountain of the unknown will long remain enormously greater than the fragments we have managed to detach and study."

On the other hand, with the characteristic sweep of his genius he was always trying to embrace wide fields of phenomena both of animal and of human cortical activity and to subject them to physiological analysis, and he would often apply the laws discovered in his experiments to phenomena far removed from the material on which those laws were originally based.

Two Points of View

As I consider this point particularly important, I should like to examine it in greater detail. Up to now experiments in the field of higher nervous activity have been concerned almost exclusively with certain specific classes of phenomena, chiefly the elaboration of conditioned associations between various external stimuli and specific reflex activities such as alimentary activity, defence activity, and so on. In this way many important experimental results have been obtained and a number of laws governing higher nervous activity established.

If we take the view that these laws can be extended to all associations between various perceptions and experiences, and that associative function (both in the sense of the formation of associations and in the sense of their fading or inhibition) represents the only cortical activity of animal or man, then the simple conclusion is that conditioned reflexes are the elements of which all this activity is composed—in other words, to revert to Pavlov's figure

of speech, it suggests that we now know with reasonable certainty the substance of which the mountain of the unknown which looms before us is made.

If this were so, then the general scheme of cortical activity in both animal and man would be mastered, and our task would consist only in interpreting and deciphering the more complicated forms of behaviour and in reducing them to their most elementary terms.

The other viewpoint (which I am rather inclined to accept) is as follows. Experimental work on animals, as well as man, in the field of higher nervous activity concerns, as I have stressed, only some particular groups of relatively simple phenomena. And there is no doubt that these groups have already been physiologically analysed more or less thoroughly, or are in the process of being so analysed. Of course, it is extremely important, and very useful, to apply the knowledge we have gained in this work to the phenomena of everyday behaviour—not only of animals but also of children and adult human beings—and to foresee the effects of various experiences on individual behaviour and welfare. This, after all, is the same procedure as that followed by the physicist who, having discovered and analysed a particular phenomenon in the laboratory, tries later to recognize and identify it in the world outside the walls of his laboratory.

But just as a scientist of, say, Galileo's day would have erred in claiming that he understood why the sky is blue or what is the mechanism of lightning—and any explanation he might have offered would necessarily be inaccurate and pseudo-scientific—so, it seems to me, those physiologists are equally in error who maintain that they understand those very complex phenomena of our cortical activity which have not yet been submitted to physiological analysis. Thus, while it is unquestionably sound and useful to winnow out from our behaviour those facts which are susceptible of physiological study, and while we should try to explain from this standpoint as much of normal and pathological behaviour as possible, we must avoid giving pseudo-scientific explanations for those facts which have not, up to now, lent themselves to physiological interpretation. It seems to me that such "explanations" are all the more harmful because they give the impression that everything has been explained and made clear in a field where there is in fact still very much to be done.

If we accept this view, and try to place Pavlov in his historical perspective, I should say that his role can be compared with that of Lavoisier in chemistry and Galileo and Newton in physics.

Just as Lavoisier, and not the alchemists, pointed the way to modern chemistry, and Newton rather than Aristotle showed the way to Einstein and Rutherford, so, I believe, the work of Pavlov will prove to have opened up the true paths towards the objective investigation of animal behaviour, and he may well be regarded by future generations as the man who laid the permanent foundations of this vital branch of human knowledge.

His Work Compared with Other Lines of Approach

But now let us come back from the days of Newton and Lavoisier to our own time, and from physics and chemistry to neurophysiology, and let us see what is the position of the physiology of higher nervous activity in relation to other main lines of investigation of the central nervous functions, represented by two leading neurophysiologists of this country, Sir Charles Sherrington and Professor Adrian.

There is no great difficulty about comparing the Pavlovian line of research with Sherrington's. It is particularly interesting for the historian of science to note that, although Pavlov's research on conditioned reflexes and Sherrington's work on spinal reflexes were undertaken quite independently of each other, the approaches to their respective fields were the same. For both of them the concept of reflex action was the basis of their research, and both of them tried to deduce the central nervous mechanism of animal activity by applying well-defined stimuli or combinations of stimuli, and measuring the animal's responses to them. For both of them the organism was, so to speak, a highly complicated device capable of an extremely wide range of responses to an extremely wide range of stimuli They differed only in that, while Sherrington investigated the ready-made mechanisms of this device, Pavlov was concerned with those mechanisms which the experimenter himself had brought about. This far-reaching parallelism in their lines of investigation was of course not accidental, it arose from the fact that both of them had their roots in nineteenth-century biological materialism.

On the other hand, it is rather more difficult to draw a comparison between Pavlov's line of research and that of Adrian on the physiology of the brain. As is well known, Adrian's approach to the problems of brain physiology differs significantly from that of Pavlov. By means of modern electrophysiological methods which consist in recording action potentials in the brain, Adrian and all who follow him attack this organ, so to speak, in a *direct* way and try to discover what is going on in the brain during its activity. Adrian is therefore not concerned, as Pavlov was, with hypothetical mechanisms of the brain deduced from external responses of the animal, but deals with the brain activity itself as recorded in action potentials.

Here perhaps lie both the strength and the weakness of this approach. The strength consists in the fact that any scientist much prefers to deal with factual evidence than with even the most fully elaborated and attractive hypotheses and theories. The weakness lies in the fact that, owing to the high complexity of the organ and its function, the evidence we obtain is as yet largely unintelligible Indeed, so far, it represents nothing more than some fragments of a magnificent and extremely complicated mechanism, but we are still unable to find from these fragments how this mechanism functions.

I think that the following comparison might be helpful in suggesting the relation between Pavlov's and Sherrington's lines of research on the one hand and Adrian's on the other.

Imagine that our task is to discover what is going on in a certain huge and complicated secret factory without being provided with clues. On the one hand, we could do it by examining both the raw material supplied to the factory and the products delivered from it. If we were allowed to do this we might change the raw material in order to see what changes there would be in the products, or even destroy some parts of the plant in order to see how that would affect production From all this evidence we could form some idea how this factory works. Of course these conclusions would be only hypothetical, and must change according to our further knowledge of the factory. But, at the same time, in this way we could have a fair picture of what this factory was intended for. On the other hand, we could find a way into the factory and watch the machinery at work. This, one would imagine, would bring us nearer to a comprehension of the functioning of the plant, but as there would be no guide to explain to us the logic and sequence of the processes of production it might happen that we should be at a loss—seeing all the details but unable to understand the whole.

And so, it seems to me, genuine progress in our understanding of that most astonishing and perhaps also the

most mysterious of all mechanisms on earth, the brain, will be reached when these two lines of investigation, from outside and from inside, converge and coalesce—in other words, when we are able to express in Adrian's terms what is going on in the brain when the conditioned reflex is established or elicited and, vice versa, which behaviour patterns correspond to the particular patterns of brain activity recorded by particular action potentials.

Some Memories of Pavlov

I should like now to recall some of my memories of Pavlov from the time when I was working with him in the early 'thirties.

When anyone has achieved as much as Pavlov, and has left a legacy as significant both in scope and in ideas as his, we are naturally curious to know how and why he did it—to know what were the psycho-physiological qualities that made such achievements possible.

He is universally recognized, of course, as a genius. No one who had ever had the opportunity of meeting him could fail to be aware of it even without knowing who he was. And, what is more, that first impression did not fade when one came to know him better—as so often happens with the great of this world. After working under him for two years I still felt for him the same admiration he inspired when I first met him. If anything, that admiration had grown and become deeper. And others who worked with him have told me they had the same experience.

But merely to say he was a genius is to use an intellectual abbreviation, to give a rather too general idea of his achievements and of the impression he made on his contemporaries. For the word does nothing to explain how his work was done and in what particular qualities lay the secret of his unique position in his field.

His Surgical Skill

To begin with one of his most immediately striking qualities, I should like to remind you that he was a brilliant surgeon. Of this I have, unfortunately, only second-hand knowledge. By the time I came to work with him he had already given up performing operations. I have been told, however, that it was an extraordinary experience to watch him at work. His surgical precision, style, and unfailing certainty were fascinating. But it was far from easy to act as his assistant during an operation. For one thing, he operated mainly with his left hand, which made it extremely awkward for the assistant. (Pavlov, by the way, could use either hand with equal skill; he wrote, for example, with his right.) The other factor which made work with him difficult was his speed. Assistants simply could not keep pace with him. This was inclined to throw him into fits of temper which he could not conceal, and which made his unhappy assistants nervous at times to the point of sheer clumsiness. I have read in some memoirs of Pavlov that, once when he was demonstrating the rather complicated so-called "Pavlovian pouch" operation on the stomach in the presence of a foreign guest, the guest thought that Pavlov was still in the first stage of the operation when it was, in fact, almost finished.

Some idea of the surgical skill which he showed at the very beginning of his career may be gathered from the fact that the discovery of the secretory nerves of the pancreas had to wait many years for confirmation simply because no one succeeded in performing the necessary operation—although Pavlov himself demonstrated it quite frequently to his students.

To a physiologist surgical skill is, of course, of the utmost importance, because it enables him to bring his ideas to realization. We know definitely that many of Pavlov's achievements were due to his surgical technique, especially in the first stage of his research, when he was working on the digestive glands.

His Capacity for Work

Another important facet of his personality was his extraordinary capacity for work. At the height of his powers he was utterly tireless. The whole of the work carried on in his laboratories, where several dozen research workers were employed, was done not only under his direct control but also with his personal participation. He himself once said, "Up to the age of 75 I didn't know what it was to be tired"; and I am sure that this was not an overstatement, for he had no liking for exaggeration.

Then there was his astounding memory. I do not know whether, by the time I knew him, his powers of memory had been diminished at all by his age, but I do know that even then he had a better memory than any of the people who worked with him. He could remember not only the names and patronymics—according to the Russian custom (*imia i otchestvo*)—of all his present and past students (an achievement he liked to boast about from time to time) the names of the dogs used for experiments, and the particular experiment performed on each dog, but he also remembered practically everything he had ever heard. And, in any case, he certainly remembered everything he wanted to remember. He never made notes, but he never forgot to return records he had borrowed and had promised to bring back by a certain time, or to be present at an experiment he had promised to watch. I believe that he alone was capable of grasping the whole scope of the research work done by his school, and he stored in his memory an astonishing number of facts.

His Quality of Mind

But all these qualities, admirable and essential as they were for achievement of Pavlov's order, were not enough in themselves to determine the essential quality of his genius. There still remains something more, something extremely difficult to define, which, for want of a more exact word, we can only call "quality of mind." Pavlov's "mind" was extraordinarily rich and many-sided.

It is well known that the work done by his school was animated and guided by his thoughts and ideas—a fact which was always gratefully acknowledged by his pupils in their papers. And his own articles and lectures always bore the imprint of his personal concepts, hypotheses, and syntheses, some of which formed the basis for entirely new lines of investigation undertaken by his followers. And yet all this written material represents only a small part of what he had to say. The richness of his ideas, the quickness of his thought, his extraordinary vision and inventiveness—all this could be fully appreciated only by those who came in contact with him and had the opportunity of listening to him or talking with him. He was always ready for a discussion, and whenever he was not engaged in experiments he was prepared to talk over either problems closely connected with the experimental work of the laboratories, or more general questions such as the potential scope and practical applicability of the study of conditioned reflexes. Such discussions—an everyday feature of his laboratories—created a highly stimulating atmosphere for collective work, and gave everyone the

satisfaction of sharing in the work of the school as a whole.

Pavlov came upon his discoveries by the process which Newton so modestly described as "continuous thinking on a subject." The modesty of this definition may suggest that anybody who is prepared to exercise his mental faculties in "continuous thinking" may do so at will. This of course is not so, for continuous thinking on a subject is precisely that which many—if not most—people cannot do. In Pavlov's case I had the impression that thinking was something he just could not help doing—a passion which he could not resist. And this passion was fed because thinking came so easily to him, and was so fruitful in new ideas, that, to use his own term, it was constantly being "reinforced" by the positive results of his discoveries.

It was characteristic of Pavlov that he had no liking for unsolved problems and would rather find a temporary solution than no answer at all. It was indeed particularly interesting to follow the process by which he gradually modified and developed his ideas until they satisfied him. And here, if I may digress, I should like to recall an incident which I myself witnessed. One of Pavlov's collaborators, a woman of a rather not very critical mind, came once to ask him for an explanation in connexion with an experiment she was engaged on. Pavlov, busy at the time with something else, got rid of her with an obviously incorrect and even somewhat naive explanation. When, later, he was discussing her work with her, she quoted his "explanation." Pavlov was furious and demanded, "Who told you such rubbish?"—then roared with laughter when he learned that the "rubbish" was his own words.

Pavlov showed a great deal of elasticity in the formation of his concepts. He was ready to admit mistakes and to renounce ideas—even when they were well established or dear to him—if he suspected that they might be wrong. Even when he was fervently defending a certain concept and when it appeared he was professing it dogmatically, he never entirely suspended his faculty for self-criticism and even scepticism. He could see himself and his school with detachment and he was able to say that for certain problems "we are already too rusty" and that others would have to try to solve them. That was why he liked to see his pupils go their own ways and break away from the routine of the school. He knew how to give them wise encouragement, but he also knew how to subject them to sharp and vehement criticism. And so far as his school was concerned, he saw to it that all work published under its auspices remained in harmony with his teachings.

I remember a conference at which a well-known Soviet histologist attacked Pavlov's theory of cortical localization on the basis of recent histological evidence. Pavlov defended his theory with extraordinary energy, ruthlessly demolishing his opponent's arguments. It seemed as if he was as convinced as his audience that the counter-arguments he was putting forward were irrefutable. But those who knew him were certain that he would not forget his opponent's objections. And in fact, when at one of his weekly conferences Pavlov read a paper on conditioned reflexes (intended, I think, for an encyclopaedia) and was asked why he had omitted his theory of cortical localization, he replied that in this paper he wanted to deal only with things he was absolutely sure of, and did not think that theory sufficiently proved. And he proceeded to quote the histologist with whom he had argued so strongly.

This gift for self-criticism, combined with his creative powers, enabled him to see problems from so many aspects that all his scientific speculations had an air of uncommon wisdom. He had also a gift for plain, concise speaking enlivened with an enthusiasm which carried away his audiences, but he hated the use of words for their own sake or in order to secure a mere effect. Once he told one of his more loquacious assistants, "You are in the power of words." And even when I came to know him his speech was free from the repetitions characteristic of advanced years.

His natural charm, the love of scientific work which was radiated by his whole personality and infected others with his ardour, his wisdom and simplicity—all these qualities gave him a singular power over all who came into contact with him. And to these we must add a talent for teaching and a strong administrative sense which enabled him to co-ordinate the work of many collaborators in the one single, monumental achievement of his school.

Pavlov the Man

I have tried to touch on the most characteristic of those features of Pavlov's intellect and personality which, to my mind, made up his genius. I have no illusions about the fact that they are far from complete and that there are many facets of his complex personality which I have not mentioned. I also realize that the picture I have sketched of this great scientist may seem somewhat one-sided, for I have paid little attention to Pavlov the man. It would, I am afraid, have been quite impossible for me to do so. I should like only to add that of all the things I admired in him it was perhaps his humanity and simplicity that attracted me most. Those qualities manifested themselves in all he did—whether he was expressing doubt about his own attainments or glowing with enthusiasm and the dynamic faith of youth after having obtained some unexpected results, or whether he was giving way to his weaknesses, quarrelling and obstinately sticking to his point even when his error was obvious—only to admit his fault when he had cooled off.

Conclusion

I should like to finish by quoting extracts from Pavlov's message to young scientists—words which I think are of interest to us all, and which perhaps express his personality better than anything I can say.*

"What would I wish for the youth of my country who devote themselves to science? First of all—consistency. . . . I can never speak without emotion of this most important condition for fruitful scientific work. From the very beginning of your work train yourselves to be strictly systematic in amassing knowledge. Learn the A B Cs of science before attempting to ascend its heights. Never reach for the next step without having mastered the preceding one. Never attempt to cover up the gaps in your knowledge by even the most daring conjectures and hypotheses. No matter how the colourings of this bubble may please your eye, it will inevitably burst, leaving you with nothing but confusion. . . . Study, compare, and accumulate facts. No matter how perfect a bird's wing, it could never raise the bird aloft if it were not supported by air. Facts are the air of the scientist. Without them you will never be able to soar. Without them your 'theories' are useless efforts. Yet while studying, experimenting, observing, try not to stop only at the surface of facts. Do not become an archivist of facts. Try to penetrate the mystery of their origin. Seek persistently the laws governing them.

"Secondly, modesty. Never think that you already know everything. No matter in what high esteem you are held, always have the courage to say to yourself: 'I am ignorant.' Don't allow yourself to be overcome by pride. On account of pride you will be stubborn where it is necessary to be

*Translation of Horsley Gantt.

conciliatory; you will reject useful advice and friendly assistance; you will lose your sense of objectivity. In the group which I am called upon to direct, atmosphere is everything. We are all harnessed to one common cause, and everyone furthers it to the best of his strength and ability. Frequently we cannot distinguish what is mine and what is thine, but through this our common cause only gains.

"Thirdly, passion. Remember, science requires your whole life. Even if you had two lives to give it would still not be enough. Science demands of man effort and supreme passion. Be passionate in your work and in your quests. . . ."

PENICILLIN IN SUBACUTE BACTERIAL ENDOCARDITIS*

BY

RONALD V. CHRISTIE, M.D., D.Sc., F.R.C.P.

Secretary of the Penicillin Clinical Trials Committee

In February, 1945, 14 centres were appointed by the Medical Research Council to investigate the value of penicillin in subacute bacterial endocarditis. By March, 1946, 269 patients had been treated, and the results were reported in this *Journal* (Christie, 1948). These patients have been followed for a further two years, and, in addition, 139 new cases have been treated. From the more recent results it is clear that some recommendations made in the previous report must be revised.

Results of Investigation

By March, 1946, 58 previously untreated patients had received 500,000 units of penicillin daily for one month; four (7%) relapsed or died infected. Since then another series of 71 previously untreated patients have been treated by the same system of dosage, and 14 (20%) have relapsed or died infected (Table I). No reason has been found for

TABLE I.—*Patients Treated for 28 Days with Daily Dose of 500,000 Units. (No Patient had Previously Received Penicillin)*

	No. Treated	Died with Infection Apparently Controlled	Died with Infection Uncontrolled	Relapsed	"Cured"	Average Follow-up (Months)	Relapsed or Died Infected
Before March, 1946	58	25	3	1	29	43	7%
After March, 1946 ..	71	22	2	12*	35	20	20%
Total ..	129	47	5	13	64	30	14%

* One patient relapsed with the same organism after 1½ years.

the higher rate of relapse and uncontrolled infection in the second series—in fact, it may have been due to chance—but the therapeutic implication seems to be that the standard daily dosage should be greater than 500,000 units.

A closer relation between the sensitivity of the infecting organism and the results of treatment can now be shown (Table II). When the resistance of the organism does not exceed that of the standard Oxford staphylococcus the relapse rate after 500,000 units a day is low; with slightly more resistant organisms the relapse rate increases.

More recently 18 previously untreated patients have received 2,000,000 units daily for at least one month; none of these relapsed or died infected (Table III). In none was the resistance of the infecting organism more than twice that of the Oxford staphylococcus. Another 13 patients who had relapsed after previous treatment were given 2,000,000 units a day for at least one month (Table III). The infection was uncontrolled in four, but in all of these the coefficient of resistance of the infecting organism was at least 64. The infection in another patient was eliminated although the coefficient of resistance was 32

TABLE II.—*Comparison of Results of Treatment with Sensitivity of Organism to Penicillin. (Resistance Expressed as a Multiple of the Resistance of the Standard Oxford Staphylococcus.) All Patients Received 500,000 Units a Day for 28 Days. No Patient had Previously Received Penicillin*

Result of treatment	Coefficient of Resistance						Total
	1 or Less	–2	3–6	8–16	32 or More	Not Known	
Died controlled ..	23	6	4	2	—	12	47
Died uncontrolled ..	—	2	1	—	1	1	5
Relapsed	5*	3	2	—	3	—	13
"Cured"	33	12	4	2	—	13	64
Total ...	61	23	11	4	4	26	129
Relapsed or died infected	8%	22%	27%	0%	100%	4%	

* One patient relapsed with the same organism after 1½ years.

TABLE III.—*Patients Treated for 4 to 6 Weeks with a Daily Dose of 2,000,000 Units*

	No. Treated	Died with Infection Apparently Controlled	Died with Infection Uncontrolled	Relapsed	"Cured"	Average Follow-up (Months)	Relapsed or Died Infected
No previous treatment with penicillin	18	9	—	—	9	11	0%
Previously treated with penicillin	13	1	—	4	8	16½	31%

Revised System of Dosage.—These results indicate that a dose of 2,000,000 units of penicillin a day for four or six weeks is adequate in most cases. This dosage may be expected to cure the infection in nearly every patient when the coefficient of resistance of the infecting organism is not more than 4 or 8. The coefficient of resistance of the infecting organism is rarely over 8, but when it is there is a greater risk of relapse. The blood should be cultured several times both during and after treatment; if infection continues or recurs at least 10,000,000 units a day should be given. Very resistant organisms (i.e., those with a C.R of over 32) are unlikely to be controlled by fewer than 10,000,000 units a day, and may not respond to 40,000,000. Treatment with other antibiotics, alone or combined with penicillin, or the use of substances such as "caronamide," which delay the excretion of penicillin, have then to be considered.

Delayed Relapses and Reinfections.—In patients who relapse after treatment the blood culture becomes positive usually within 60 days. But in 14 patients infection recurred after periods ranging from 4 to 50 months, and in five of these the second infecting organism clearly differed from the first. Many patients have now been followed up for four years, and the incidence of delayed relapse or reinfection among them has been found to be about 2% per annum.

Bacteriologically Negative Cases.—Only the 408 patients with a positive blood culture have so far been considered, but reports of 35 patients with negative blood cultures have

*Report to the Medical Research Council on 408 patients treated in 14 centres appointed by the Penicillin Clinical Trials Committee.

been collected by six of the centres (Table IV). Three facts have been established: (*a*) with the comparatively small doses of penicillin used only 6 of 26 previously untreated patients were cured; (*b*) the fever returned or was not controlled in 11 of the 26 previously untreated cases; (*c*) in the 13 who died with uncontrolled fever, organisms were seen post mortem in the vegetations of 6. It is not known whether larger doses will produce better results, but it is

TABLE IV.—*Bacteriologically Negative Cases*

	Dosage	No. Treated	Died with Fever Controlled	Died with Fever Uncontrolled	Fever Returned	"Cured"
No previous treatment with penicillin	2,000,000 units for 1 month or more	2	2	—	—	—
	500,000 units for 1 month (approx.)	15	5	6	3	1
	250,000 units for 1 month (approx.)	7	2	1		4
	Unclassifiable	2		1		1
	Total	26	9	8	3	6
Previously treated with penicillin	2,000,000 units for 1 month or more	1		1		
	500,000 units for 1 month (approx.)	4	3	1		
	250,000 units for 1 month (approx.)	2		2		
	Unclassifiable	2	1	1		
	Total	9	4	5		

suggested that these patients should be given 2,000,000 units a day and that the dose should be increased if the clinical response is unsatisfactory. In view of the importance of establishing the coefficient of resistance of the infecting organism it is unwise to abandon blood cultures until at least three have proved negative. An anaerobic culture should always be included.

Factors Affecting Prognosis.—In general the recent results confirm the conclusions regarding prognosis and causes of death discussed in the previous report. A detailed analysis of these patients will be incorporated in a review of the subject which is now being prepared.

Conclusions

Patients with subacute bacterial endocarditis should be given at least 2,000,000 units of penicillin a day for a month or six weeks.

When the infecting organism is highly resistant to penicillin, or when it cannot be isolated, it is difficult to estimate the appropriate dose. Some factors involved in making this assessment are discussed.

The incidence of delayed relapse or reinfection is approximately 2% per annum.

REFERENCE

Christie, R. V. (1948). *British Medical Journal*, **1**, 1.

According to a report (B.U.P.) Dr. Robert Coghill, who played an important part in the development of penicillin mass-production, told a meeting of the American Chemical Society that, although 200 antibiotics had been investigated, only six have appeared on the market, and of these two are of limited use only. While the term "miracle drug" could legitimately be applied to penicillin, Dr. Coghill stated that the chief miracle in connexion with one or two currently used antibiotics would be if they were still in use in five years' time. He added, "The truth of the matter is, unfortunately, that the vast majority of antibiotics are for a variety of reasons utterly worthless for human therapy."

SUDDEN OBESITY AND PSYCHOLOGICAL TRAUMA

BY

H. J. SHORVON, M.B., D.P.M., D.A.

Assistant, Psychiatric Department, St. Thomas's Hospital; Psychiatric Specialist, Belmont Hospital

AND

JOHN S. RICHARDSON, M.V.O., M.A., M.D. F.R.C.P.

Physician in Charge of Out-patients, St. Thomas's Hospital

It has long been recognized that loss of weight can accompany psychotic and psychoneurotic illnesses such as depression and anorexia nervosa. Clinicians also meet atypical cases of depression in which there is an increase of weight, and this has been vaguely linked with endocrine disturbances, such as may occur at the female and male climacteric. This paper is concerned with a group of cases showing a sudden onset and rapid development of obesity, with or without amenorrhoea and menstrual disturbances, which gives rise to a syndrome of obesity, anxiety, tension, and depression.

The investigation first arose when it was observed that some obese patients who failed to respond satisfactorily to the usual methods of treatment dated their obesity and also some psychoneurotic symptoms to a specific incident that might well have inflicted psychological trauma. We found that too little attention had been paid to the emotional factors in the first instance, and the patients had been treated on an organic basis for long periods. We do not claim that the treatment pursued with this group is primarily aimed at reducing weight, but we have used it to alleviate the associated mental distress and have found that patients often show a parallel reduction of weight and become more amenable to accepted methods of treatment of obesity.

The problem of obesity has been extensively investigated by physiologists for many years, and no essential underlying disorder of metabolism has been convincingly demonstrated. Newburgh (1942) reviewed the subject and came to the conclusion that excessive intake of calories with reduced activity could account for almost every case. He explained the irregularity of loss of weight when on a strictly limited calorie intake as being due to fluid retention, and quoted an example that demonstrated this point clearly.

Effect of Lesions of the Hypothalamus

Lesions of the hypothalamus in animals in which the anterior lobe of the pituitary has either been removed or left intact result in obesity (Hetherington, 1943). This obesity does not, however, follow extensive damage to the hypophysis provided the hypothalamus is intact. These clear-cut experiments of Hetherington's have solved the controversy that has lasted for over 30 years between Fröhlich, who maintained that damage to the hypophysis was the necessary factor, and Erdheim, who believed the essential lesion must be in the hypothalamus. Animals that have had suitably placed lesions in the hypothalamus not only show an increase in appetite that accounts for their obesity in almost all instances, but the manner in which they eat their food changes from the normal habit of the species.

The appetite of the animals operated on is described as voracious, savage, or wolfish by various authors, and rats

that normally store their food and eat it by night will devour every morsel immediately it is dropped into their cage. The increased intake of food accounts for the increase in weight when the animal is fed *ad libitum*. But a small proportion of rats whose food is restricted show some minor increase in weight over the control animals, indicating that in them a mechanism other than increased intake is operating. This may be related to the change in feeding habits to which we have already referred, as Tepperman *et al.* (1943) have shown that normal rats will convert glucose into fat at an accelerated rate if the animals are trained to eat their normal 24-hour portion within a short time.

It has also been shown that rats with a hypothalamic lesion and hyperphagia had exceptionally high R.Q.s—well over unity during the absorption of glucose, indicating that most of the carbohydrates were being converted into fat. This phenomenon develops only gradually within the first week after operation (unlike the increase in appetite and the temperament changes, which can be observed almost before the animal is out of the anaesthetic), suggesting that it is the result of the altered feeding habit and hyperphagia. A marked change in temperament as well as in appetite has been observed in these animals, and they may become aggressive and savage.

The effect of emotions acting through the hypothalamus in man has been well demonstrated by Verney (1946) in his series of experiments on the action of the antidiuretic hormone of the posterior pituitary. He has shown that emotional stress, by acting on the hypothalamic nuclei, releases from the pituitary the antidiuretic substance, and has suggested that conditions associated with low sympathetic tone in man might be favourable to prolonged secretion of the substance. His experiments may explain the undoubted retention of fluid that is shown by many obese subjects who have no organic lesion of the hypothalamus but in whom emotional disturbances may have produced effects on the hypothalamic nuclei.

The enormous increase in appetite and very definite alteration in temperament and activity of animals with organic lesions of the hypothalamus may be in part mirrored by our patients through stimuli coming from the higher senses acting on the nuclei in the hypothalamus in a manner similar to that already demonstrated by Verney in his work on the supraoptic nucleus. Thus there is a background of evidence from careful physiological observations to account for our finding that violent emotional stress may result in rapidly developing obesity.

The following three cases are representative of the group we are studying.

Case 1

A woman aged 38 complained on admission to hospital in June, 1947, of rapid increase of weight and amenorrhoea since suffering a very severe shock in 1943, with a further increase in weight in 1944 after a narrow escape in a bomb incident. At the same time she complained of an inability to pass sufficient urine, difficulty in concentration, and poor memory. Her father died, aged 58, from coronary thrombosis and "urinary retention." He was a military bandsman, a strict disciplinarian, and short-tempered, and would beat his children. He taught them to hide their feelings. Her mother had a "cold temperament," would not accept her children's confidences, discouraged their emotion, but gave in to their wishes. There was little love between the parents, only duty. She had a lonely childhood and average schooling, and was always afraid of expressing any emotion. She was a student teacher till 18, then studied music and passed her L.R.A.M. For a while she earned her living as a piano-teacher and gave piano recitals. She married three times.

The first marriage, at 18, was to a man 14 years her senior, who was irresponsible, "too sexual for her immature years," and constantly in debt. He died 14 years ago. They had two children, a girl—a brilliant child who died in 1943 at the age of 13 from a sarcoma of buttock—and a boy, now aged 14. The second marriage was a failure, as her husband was impotent, had "brain storms," and led her a "shocking life." In order to keep the peace for her children's sake, she says, she had to shut out her emotions and give up piano-playing because it irritated him; and to be away from him as much as possible she joined the police force in 1939, as she was a tall, powerful woman brought up to appreciate discipline and order. This marriage was annulled after five years' misery. The third marriage, in 1945, was to a police sergeant. It was satisfactory at first, but she soon became frigid, and now feels socially and intellectually her husband's superior, although she loves him.

In 1943 she experienced a severe shock when told that her daughter had a sarcoma of buttock and had only a few months to live. "I showed no emotion. I did not feel any. I was dead." Her periods stopped and she was "mentally distressed and began to swell." She increased in weight from 12 to 19 st. (76.2 to 120.6 kg.). The amenorrhoea lasted three months, and after that she saw only a few spots. The child lay ill at home for months, and required frequent morphine injections. The patient stayed up with the child most of the night and then had to go on duty. She kept up appearances before the child, but also experienced strong feelings of guilt because of previous lack of affection for her.

In 1944 she experienced another severe trauma. While on duty alongside an escalator at Waterloo Station a flying bomb crashed near her and there were numerous casualties. She was blown over and then took part in the rescue work. Three weeks later she collapsed and was taken to hospital, where she had a rest for three months. After the bombing incident her weight increased from 19 to 20 st. (120.6 to 127 kg.). She was given stilboestrol injections and had a very scanty cyclical bleeding. Her emotional tone returned and she began to grieve for her daughter and reproach herself. She had to give up work after a few months and was investigated for a possible pituitary lesion at Guy's Hospital, but the findings were negative. Two years ago she began to receive regular injections of "neptal" and lost weight rapidly. With regular injections for two years her weight went down to 13 st. (82.5 kg.); but the effect diminished, and before admission to hospital she went up to 14 st. 8 lb. (92.5 kg.). She remained tense, felt confused and exhausted, and had not worked for over a year. There was an absence of libido.

On physical examination her weight was 14 st. 8 lb. and her obesity was of the simple type with normal feminine distribution. There were no signs of organic disease either in her endocrine or her cardiovascular system. The blood pressure was 140/80 and her urine contained no abnormal constituents.

On psychiatric examination she volunteered the information that her "inflated condition" depended on whether she was mentally relaxed or not, and said she was convinced that the mental illness caused the physical illness. She complained of a tight feeling in the head, but stated that she had taught herself to school and control herself, but it required a great effort. "I have often thought I require an emotional release."

She experienced considerable mental relief from a discussion of events and symptoms under sodium amytal narco-analysis. She was then abreacted under ether, the bombing incident supplying the starting-point of the abreaction. There was a violent emotional release as she re-enacted the scene, accompanied by piercing shrieks when she described the flying bomb coming down. An amnesia for events connected with the incident was uncovered, and she revealed the conflict at that time between her duty and her own and her child's safety—she could not decide whether to run for shelter when she heard the bomb. The day following the abreaction she said she felt entirely different; her mind felt clear, and she decided to resign from the police force in order to be "more feminine" to her remaining child. She also resumed her music-playing (she had not played at all since the start of her illness). The ether abreaction

was repeated twice, with further release of affect. When she left the hospital her weight had fallen to 13 st. without any dietary restriction, and she resumed her previous occupation of teaching music. A fortnight later she had a menstrual period which lasted three days, and she described this as the most normal she had had for four years.

This case of sudden onset of gross obesity with water retention and amenorrhoea, following a clear-cut psychological trauma and exacerbated by a second, illustrates the benefit that can be obtained by an abreaction of the precipitating events.

Case 2

A woman aged 30 complained in 1948 that she was very worried by her rapid increase in weight from 10 to 15 st. (63.5 to 95.3 kg.). This took place over a period of some months five years previously and followed the shock of the sudden death of her mother. There have been only minor fluctuations in weight since then.

At the first interview she stated that her father was a nervous, lonely, sanctimonious man who had had a nervous breakdown in the 1914–18 war. She was afraid of him because of his very violent temper and frequent quarrels with his wife. She was extremely fond of her mother, a hard-working woman who suffered from migraine and died from a cerebral haemorrhage at the age of 48. There is one brother, a medical student. The patient was a nervous child, a nail-biter, with fears of the dark. She had a normal schooling, mixed well, and did secretarial work before her marriage. Her characteristics are described as knowing her faults and liking to be the centre of interest. She married at the age of 21, and has daughters aged 7 and 2 and a son of 5. She claimed that the marriage was a happy one, although she had not experienced any sexual satisfaction and her husband frustrated her by the methods he adopted. Her health was good, but she had operations for uterine prolapse in 1946 and 1947.

In October, 1943, she was in a nursing-home awaiting tonsillectomy and was visited by her mother. The next day she was told of her mother's sudden death. "I always remember the shock. I could not believe it. I am always thinking of her. Even now I imagine I see mother." From this time she put on weight rapidly, was unable to reduce effectively despite numerous therapies, and felt very sensitive about her figure. She denied that she ate excessively, and alleged that dieting did not help her. She admitted that she had had a large appetite in the past. She also developed a troublesome itching rash on the inside of her legs and a pruritus ani which disturbed her sleep.

On physical examination her weight was 15 st. and her obesity was of the simple type, the chief excess of fat being on the buttocks (upper part) and on the abdomen. Her skin was soft and her body hair scanty. Her blood pressure was 160/100, and her urine contained no abnormal constituents. There was no evidence of any endocrine disorder. Her dietetic history showed that at this time she was taking a diet of approximately 2,500 calories, with an excess of carbohydrate.

On psychiatric examination she was tense and anxious. She felt lonely, frustrated, and tired, and experienced bad dreams in which she generally harmed her children. She complained that she screamed at the children and "could kill them." She was treated by sedation and a weekly series of ether abreactions which are set down here in some detail.

In the first treatment she described her aggressive feelings towards her second child (the obesity began eight months after this child's birth). The main emotional release, however, was over her mother, in whom, at this stage, she stated she had always confided. In the second abreaction the patient exhibited a good deal of rage when discussing her husband. He calls her "Tiny" and irritates her with his lack of understanding and complacency. She wished she were back to her schooldays, when she was known as "Starving Russia." In the third abreaction, after going over old ground, she suddenly abreacted violently over her mother's death and screamed, "What do they do at a post-mortem? The wounds do not heal like ordinary operation wounds." She regretted not having her mother cremated, and visualized her in a cold grave. The fourth abreaction was mainly over a comparison between her husband and her father, whom she hated, but this she denied as soon as she had expressed her loathing. She felt less tense after each treatment, and lost 10 lb. (4.5 kg.) in the 24 hours after the first, and had lost 1 st. (6.4 kg.) after four weeks without any attempt at dieting. She thought it was due largely to fluid loss. In the past, strict dieting had been a failure, and in any case she was unable to keep it up for any length of time. The irritating rash was ameliorating, and "although far more preoccupied with thoughts was also far more able to deal with them."

She began dreaming about her mother, and the fifth abreaction ranged over this and the post-mortem examination. The next abreaction was over an elderly spinster neighbour who had been dominating her for some time and referred to her as "my adopted daughter." She felt this woman had replaced her mother.

It is interesting to note that at this stage her attitude towards her mother was beginning to change. The ensuing abreactions were mainly concerned with her marital difficulties, guilt over recent masturbation, her ambivalent attitude towards her father and her husband, and general feelings of frustration and hostility.

From the eleventh abreaction she began to talk more freely about her mother, and at the fourteenth abreaction was showing resentment. She described her feeling of desolation and resentment when her mother suddenly left her in a boarding-school at the age of 7 and went abroad to her husband for two years. She also disclosed: "I was never allowed to have an opinion of my own." Her mother did not approve of her marriage and "bred deceit"—"sex was taboo, and I had to do everything underground." By the fourteenth abreaction she had lost 2 st. (12.7 kg.) in weight and was showing an appraisal of the situation regarding her mother. She was gradually freeing herself from the mother's dominating influence, and at the present time is continuing treatment.

Case 2 illustrates the unsatisfactory mother–child relationship often found in obese subjects. The trauma of the sudden breaking of this tie was sufficient to start off gross increase in weight. After a series of abreactions she was not only improved from the psychological standpoint but had lost 2 st in weight without any other form of treatment

Case 3

A woman aged 48 was first seen in March, 1946, when she complained principally of obesity, "blackouts," headaches, fits of depression, swollen ankles, and insomnia. She stated that her weight went up from 11 to 16 st. (69.8 to 101.6 kg.) after the birth of her last child in 1942. Her periods were regular up to 18 months ago, but she had had only three scanty ones in the past seven months.

Her father was a regular soldier and strict disciplinarian who would not allow her to answer back, and her mother is described as "very sweet." The patient, one of seven siblings, was brought up very strictly, knew nothing of sex or menstruation, and was ignorant on such matters at her marriage. She had an excellent school record and, apart from smallpox at the age of 5, had good health. After the death of her first husband, when she was 26, she trained as a mannequin because she loved clothes, and did exceptionally well as a freelance for several years, but in 1932 her second husband compelled her to give it up. He bought her two tobacconist shops, which she managed successfully till 1939. The business failed early in the war and she became an ambulance nurse, but since her last confinement she has worked as a housing officer and Civil Service clerk. When well she is said to be full of confidence, energetic, hard-working, capable, a good mixer, over-conscientious, meticulous, fastidiously clean, and gay with a strong libido.

Her first marriage, at 17, was a happy one and lasted nine years, when her husband died from pneumonia. There are three children of this marriage. The second marriage, five years later (1932), was a ghastly failure, and ended with the

husband's suicide in 1937. He was an aggressive psychopath, terribly jealous and possessive, and constantly threatened to murder her and commit suicide. He insisted on perverted sexual relations with her, drank heavily, beat her, and on several occasions tried to gas her. She had a depressive spell with "blackouts" and loss of weight for some months after his death, but soon recovered her old interests and married a third time in 1939.

The history of obesity dates from her confinement in 1942. She had toxaemia during pregnancy and underwent a prolonged induction of labour, during which she became very frightened and was convinced she was dying. In the puerperium she developed pneumonia and femoral thrombosis followed by emboli in the lungs and right kidney. At this time the hospital was bombed; windows were blown in around her, and she was carried into the corridor. She was a semi-invalid for 18 months after leaving hospital, gained 2 st. (12.7 kg.) in weight during the first year and steadily after, despite constant anxiety and numerous traumatic incidents occurring throughout the war. Her son was reported killed at Arnhem in 1944, but she later learned that he had become a prisoner of war and that he had advanced tuberculosis. Another son was torpedoed three times and is badly disabled, and she had to help support both sons. Her home was blasted four times. She also underwent numerous stress incidents while on ambulance duty during the raids and in the flying-bomb periods, but she continued to work most of the time. Two years ago, soon after the return of her glider-pilot son, she became worried, was afraid to be alone at night, felt that her husband was turning against her, and became depressed. She could not concentrate; she became forgetful, and complained of occipital headaches, dyspnoea on exertion, sleep-walking, frequency, and "blackouts" about once a fortnight. She also had transient unreality symptoms—"a blankness of mind and a feeling of walking on water."

On examination the obesity was simple in type and was most pronounced on the buttocks. The cardiovascular system and C.N.S. were normal. Her blood pressure was 120/70. Urine: n.a.d. She was very tense, anxious, depressed, and hypochondriacal. She had previously reduced from 16 st. to 14 st. 9 lb. (93 kg.) by diet, but on admission weighed 15 st. 1¼ lb. (96 kg.). She was taking a well-balanced diet of approximately 2,000 calories.

An intravenous sodium amytal narco-analysis was concerned with many distressing experiences, particularly in air-raids: in one flying-bomb incident she felt sure her young baby was killed. After the investigation she tended to dissociate. Some days later she abreacted under ether, and there was a violent emotional release with screaming and weeping. She had some amnesia for the flying-bomb incident, but knew she threw her baby under a falling chimney when she saw a bomb coming towards her. She wept freely after the abreaction and dissociated for about 15 minutes. She then asserted, "I feel a load off my mind," but was unable to explain this.

She remained in a tense state, and a week later again abreacted violently under ether. There was a most intense release of emotion when she described an attempted rape by her psychopathic second husband. He tore off her clothes and slashed her with a razor, demanding a child which she refused to give him. "He tore my inside out." The next day he threw himself under a tube train and she identified his mangled body. She confessed to feeling guilt and responsibility since then, as she had threatened, and wanted, to kill him. During the abreaction she showed great rage and desire to kill him, and finally dissociated. Later she continually returned for reassurance that she was not responsible for his death and wept freely.

A week later, under ether, she was again violent with fear, horror, and rage directed against her former husband. "I'll kill you," and "Go and kill yourself," were phrases frequently expressed. She reiterated that her former husband was a beast, wept, and dissociated.

Some days later, when interviewed, she said she could now talk about her former husband without feeling guilt. She also played the piano and sang, which she had not done for many years, and no longer felt that life was not worth living. Menstrual flooding occurred after six months' amenorrhoea, and it is of interest that she had a flooding lasting six weeks after her second husband's attack on her, and she linked this similarity with the severe abreaction over her husband.

As some tension persisted she was again abreacted a week later. This was even more violent than the others; she reached an extreme pitch of excitement to the point of exhaustion, and showed little tendency to dissociate after coming round. She wept for some time and described her husband's behaviour in much greater detail. For the first time she returned to the ward without assistance.

She was now much improved and no longer worried about her second husband, but soon after became preoccupied with the flying-bomb incident previously mentioned. It was decided to attempt to clarify that situation by further abreaction. She described working in her office one afternoon when a flying-bomb swished past the windows, which were then blown in, and a filing-cabinet fell on her. When she arrived home she heard the sirens again and rushed out to reach her baby playing in the garden. A flying-bomb came down, and she held her child against the wall of a shelter. The bomb hit a near-by factory and she could see a chimney-pot coming straight at her. She threw the child into the shelter and fell, and as she did so she believed the chimney had hit and killed the child. She lost the use of her limbs and "blacked out" momentarily, then heard the child cry and crawled to him. Immediately after this episode she became very hysterical and attacked her husband for not having been present. At this stage of her treatment she had lost 11 lb. (5 kg.) in weight without dieting, and, although much better, she remained mildly tense and preoccupied with the bombing incident and was abreacted a sixth time. Further details were clarified with good effect, and there was a marked easing of symptoms. She ceased to blame herself, was able to travel in a tube train for the first time since her husband's suicide in 1937, stopped sleep-walking, regained her former confidence, and continued to lose weight each week.

Case 3 is of special interest in that the patient failed to gain weight after numerous traumatic incidents connected with her psychopathic second husband: she actually lost weight after his terrible and sudden death—a circumstance that can reasonably be attributed to relief and loss of tension. The psychological trauma that actually led to a rapid increase in weight was the bombing of the hospital in which she was a patient suffering from pneumonia during the puerperium. The abreactions in her case did not centre round the actual precipitating trauma, as it was found that sufficient affect was released by the incidents she brought up spontaneously whilst under treatment.

Discussion

Psychosomatic studies of simple obesity (Weiss and English, 1943; Dunbar, 1943) suggest that it is an "organ neurosis," its manifestation depending on constitutional factors and pre-existing fears. Fenichel (1945) in a psychoanalytical approach to the subject also regards obesity as an organ neurosis. He stresses the basic importance of exhibitionistic and pre-oedipal mother conflicts. "Oral gratification" is emphasized by many authors: the individual remains emotionally immature and overeats from early childhood. Psychological investigators into obesity in childhood emphasize the factors of lack of parental love with prolonged over-protection of the child (Bruch, 1940; Bronstein *et al.*, 1942; Gastineau and Rynearson, 1947). As Bruch points out, the child may go in for the pleasures of food if it does not get the pleasure of love from its parents.

When an individual becomes obese for the first time in early adult life, oral gratification, as a result of latent conditioning, may again allay anxiety or conflicts. Schopbach and Matthews (1945) found that most of their cases had

emotional problems and tension which produced an urge to eat, and if the urge was not satisfied the tension would mount. Freed (1947), in a study of 500 obese patients, also found strong evidence that anything which increased emotional tone increased the appetite for food. Personality studies have been carried out by various workers (Rennie, 1940; Nicholson, 1946), and include patients who fail to respond to a dietetic regime. The practical result of such studies is the conviction that a psychotherapeutic approach is a useful treatment in these cases, and attempts have been made to resolve or ameliorate factors contributing to neurotic breakdown, such as family relations, environment, social and sexual maladjustments, prolonged tension, and insecurity.

There is little mention in the literature of the influence of severe emotional stimulation in the rapid production of obesity. Bruch (1940) quotes Lichtwitz (1923) as observing during and after the 1914–18 war rapidly developing obesity in women who had been under severe mental stress. Lützenkirchen (1924) described the case of a woman of 29 who developed adiposity, diabetes insipidus, genital atrophy, and amenorrhoea after serious psychic traumata of long duration. The condition was thought to be organic, but some success was achieved in treating the case along psychological lines alone. Hochman (1938) illustrated the relation between severe emotional stress, such as the shock of the death of a parent or a financial reverse, and overeating in six cases. Greene (1946) has recorded a fascinating example in which emotional stress led to obesity, and an improvement in the patient's circumstances was followed by a reduction in her weight without any other form of treatment, although she abandoned her diet. Gilbert-Dreyfus (1948) published a survey of a large series of cases suffering from "paradoxical obesity" as a result of bombing, prisoner-of-war, or concentration-camp experiences, the increase in weight usually taking place over some weeks. The incidence was almost exclusively in women, and the trunk and abdomen were the sites mainly affected. There was considered to be evidence of water–salt retention, and a few abbreviated case records and an outline of treatment were reported.

Our cases fall into a special category in that severe traumatic incidents seem to form the direct precipitant of sudden and marked simple obesity. The connexion between the obesity and this psychological trauma in time decided us to make use of abreactive techniques, the primary object of which is to relieve anxiety, tension, and aggression. The value of emotional release in "traumatic" anxiety states by excitatory abreaction and the technique employed under ether has been described in previous papers (Sargant and Shorvon, 1945; Shorvon and Sargant, 1947). The patient relives and re-experiences the original trauma, and, if the abreactions are successful, traumatic incidents tend to lose their emotional significance and thus cease to worry the patient. Though preferable, it is not necessarily essential to abreact the specific incident or range all over the traumatic incidents, and in practice we find that even an abreaction of a non-specific kind may produce symptomatic improvement providing the emotional release is of sufficient intensity. We have applied the technique of ether abreaction to many obese patients of the kind under discussion, and this will form the subject of another paper, but the cases quoted above are examples of the method and results. There is a symptomatic improvement with pronounced easing of anxiety and loss of weight of from 1 to 2 st. (6.35 to 12.7 kg.). The method has the advantage of being quicker and more practicable than prolonged psychotherapy, and certainly requires fewer interviews. Some psychotherapy, however, is essential, as the implantation of new ideas and reintegration of the abreacted patient are very important. There is reason to believe that patients treated in this manner are then more likely to be able to observe a strict diet if this is considered necessary, and drugs such as "dexedrine" (dextro-amphetamine) may be better tolerated.

A brief analysis of the clinical findings and case histories of 12 women suffering from this syndrome is of interest. Anxiety, tension, giddiness, aggression, irritability, and depression are symptoms common to all, and many show hysterical features, such as "blackouts" and "fainting turns." The majority had stern aggressive fathers and overindulgent, over-protective, kindly but "cold" mothers, and they were brought up in a strict fashion. All assert that before marriage they were almost completely ignorant of sexual matters. A good example is the patient who developed an anxiety state at the age of 23 after she had been kissed, as she believed pregnancy took place via the mouth. It is therefore hardly surprising that among an emotionally immature group of this kind many experience little or no satisfaction in their sexual relationship, and maladjusted marriages are common. The death of a mother, an undesired pregnancy, or the near-miss of a bomb explosion were the most frequent immediately preceding psychic trauma. Menstrual disturbances following the trauma occurred in some. One young woman still has a persistent amenorrhoea, although the precipitating incident occurred five years ago, but it is more common for patients to experience a temporary amenorrhoea of some months' duration.

In a personality assessment of this series we find certain traits common to practically all—namely, immaturity, impulsiveness, lability, and a poorly organized emotional life. They present a hysterical picture with a tendency to refuse to accept their inner urges or to express them in a satisfactory manner. Further personality studies, however, on control groups showing loss in weight are necessary if one is to get a clearer view why some patients put on weight rapidly under severe stress, whereas the majority appear to lose weight under similar circumstances.

Summary

The association between the sudden onset of simple obesity and severe psychiatric trauma is illustrated by three case histories taken from a larger series of cases.

A fairly uniform personality pattern in these cases is described.

The results of abreactive techniques in treatment are discussed, and it is suggested that they may provide a useful adjuvant or preliminary to the accepted forms of dietetic treatment in certain selected cases of obesity.

Our thanks are due to Dr. P. M. F. Bishop, of Guy's Hospital, for permission to study the first case, to Dr. E. A. Burkitt for his help in treating the third case, to Dr. M. Desai for the Rorschach personality studies, and to Miss Pemberton, dietitian, St. Thomas's Hospital, for taking dietetic histories.

UPPER-LIMB PAIN DUE TO LESIONS OF THE THORACIC OUTLET*

THE SCALENUS SYNDROME, CERVICAL RIB, AND COSTOCLAVICULAR COMPRESSION

BY

LAMBERT ROGERS, V.R.D., M.Sc., F.R.C.S. F.R.A.C.S., F.A.C.S.

Professor of Surgery, University of Wales

(From the Surgical Unit, Welsh National School of Medicine)

Cunningham calls the upper opening of the thorax the inlet, the lower opening the outlet. It is assumed that we are referring to the upper opening, for there can be few if any lesions of the lower one which produce pain in the arm.

The Upper Opening of the Thorax.—The superior aperture of the thorax is a narrow opening which is bounded by the first dorsal vertebra, the first pair of costal arches, and the manubrium sterni. From it issue the great vessels and nerves to the upper limb, and interference with them at their egress by certain structures may cause pain of two kinds: that of neuralgia or neuritis, or that of ischaemia.

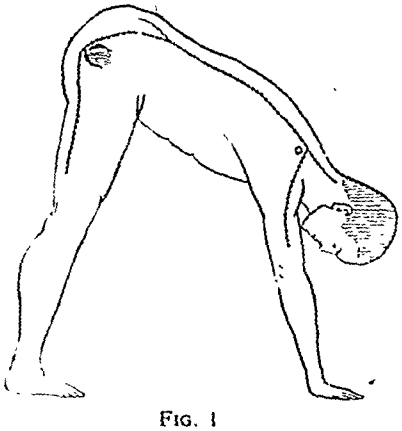

FIG. 1

FIG. 2

FIG. 1.—With the four limbs on the ground the nerve trunks of the limb plexuses enter the limbs approximately perpendicular to their origin and are neither acutely angled nor stretched.

FIG. 2.—With the assumption of the upright position the lowest of the nerve trunks of the forelimb plexus which leaves the thorax is angled acutely. The nerves to the lower limb pass almost vertically downwards and there is no tendency to angulation.

*Read in opening a discussion in the Section of Orthopaedics at the Annual Meeting of the British Medical Association, Harrogate, 1949.

Pain in the Upper Limb

Two questions to be answered are: (1) What structures may produce this interference and so cause this pain? and (2) Why are these painful conditions relatively common in the upper limb and uncommon or absent altogether in the lower limb?—because we now have definite evidence that sciatica, which of course is common enough, is not due to any lesion at the pelvic outlet but to a radiculitis that is usually the result of an intervertebral disk lesion.

Dealing with the second of these questions first, I suggest that it is man's upright posture combined with the great use of the forelimb when erect which causes the pain in the arm and accounts for its absence in the leg. As the erect position is assumed there is an angulation of the structures leaving the superior aperture of the thorax, so that they are readily stretched across any abnormal or at times even normal structure that may here form the boundary of the opening, whereas in the case of the lower limb the upright position undoes or opens out any such angulation of the neurovascular elements which enter the limb from the pelvis (Figs. 1 and 2).

Character of the Pain

Neural Pain.—This is usually of a tingling or stabbing character and of ulnar distribution. It is due to the lowest trunk of the brachial plexus being stretched over and/or compressed against (*a*) a cervical rib, (*b*) a fibrous band corresponding to a rib (Fig. 3), (*c*) the medial tendinous lower fibres of the scalenus medius (those arising from the seventh cervical transverse process), or (*d*) occasionally an abnormal scalene muscle (pleuralis of Sibson, intermedius of Testut, minimus of Albinus) lying between the artery and the nerve trunk.

The Scalenus Syndrome.—The part played by the scalenus anticus has been exaggerated, and simple division of this muscle may fail to relieve symptoms. The syndrome should be called the scalenus syndrome and not the scalenus anticus syndrome, as so frequently the scalenus medius (also the scalenus minimus less often) plays a part in its production. At operation it is essential to free the lowest trunk of the plexus from the rib, band, or tendinous scalene fibres over which it may be stretched. A frequent finding in these cases is an abnormal origin of the posterior scapular artery from the third part of the subclavian. The artery passes between the trunks of the plexus and tends to hold down the lowest trunk against the structure over which it is stretched (Fig. 4).

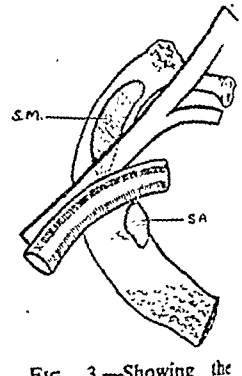

FIG. 3.—Showing the relationship of the lowest trunk of the brachial plexus to the lower medial tendinous fibres of the scalenus medius.

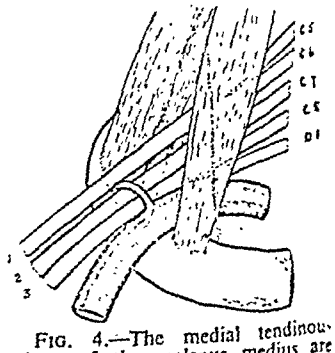

FIG. 4.—The medial tendinous fibres of the scalenus medius are shown and the abnormal posterior scapular artery arising from the third part of the subclavian and passing outwards and backwards between the trunks of the plexus so as to hold the lowest trunk against the subclavian artery.

Vascular Pain.—This is usually of a dull aching character, and is due to a relative ischaemia brought about by compression of the subclavian artery (the costoclavicular syndrome).

The Costoclavicular Syndrome.—Interference with the blood flow in the subclavian artery at the

thoracic opening is the consequence of the artery being compressed, when the arm is placed in certain positions, between the clavicle and either the first rib or a cervical rib. Elevation or depression of the shoulder may open out or diminish the space between the bones, according to the shape of the upper thoracic opening as modified by the abnormal rib (cervical or thoracic). While this is probably the explanation in most cases in which the syndrome is well developed, a minor degree of compression may be produced by the scalenus anticus, the artery being compressed between the contracted muscle in front and a rib or band or even the scalenus medius behind (Murphy, 1906; Wingate Todd, 1911).

An alternative hypothesis has been suggested by Wingate Todd (1913), Telford and Stopford (1930), and others, that irritation of the sympathetic fibres accompanying the lowest trunk of the brachial plexus may account for the vascular symptoms by inducing vasospasm, but there is little evidence in favour of this, and recently Sunderland (1948), of Melbourne, who has investigated the question by histological studies of the brachial plexus in some cases in which the syndrome had been present, finds no support for this view.

Other Aetiological Factors.—In addition to abnormalities of the upper thoracic opening, certain other factors may contribute to the appearance or the severity of either the scalene or the costoclavicular syndrome by leading to the depression of the shoulder girdle and thereby increasing the angulation of the issuing nerve trunk and artery. This may come about as the result of: (1) The dropping downwards and backwards of the shoulder girdle which takes place in late adolescence. (2) A downward pull on the shoulder as by a post-bag (Maddox, personal communication, 1946) or, as was seen early in the war when respirators were worn constantly, the respirator strap (Rogers, 1941a, 1941b). Long ago, de Quervain (quoted by Cushing, 1903) noted that rifle drill produced the syndrome in some young recruits, and even the direct pressure of a violin on the root of the neck has been productive of symptoms (Sheen, 1912). (3) Fatigue which may lead to an atonic condition of the supporting muscles of the shoulder girdle.

Diagnosis

Diagnosis is usually evident. A young person who has numbness and tingling in the hand and fingers and along the ulnar border of the forearm, aching around the shoulder girdle, and flattening of the thenar eminence, whose symptoms are relieved by elevating the arm, and whose radial pulse may be obliterated or diminished in volume by stretching the arm well above the head, presents a typical picture, particularly if the symptoms have developed in late adolescence, after losing weight, or after some unusual dragging on the arm or depression of the shoulder as in carrying a respirator. *X*-ray films may show the presence of cervical ribs or of large costal processes the ends of which are pointed and directed downwards and outwards. They may also indicate abnormalities of the thoracic inlet, and it must be remembered that the first rib may be the cause of symptoms in some cases. Sometimes the subclavian artery can be seen elevated in the supraclavicular triangle so that its pulsations are apparent and may even resemble those of an aneurysm.

Differential Diagnosis

The syndrome must be differentiated from ulnar neuritis, herniated cervical nucleus pulposus producing a radiculitis, and writers' cramp.

Ulnar Neuritis.—In ulnar neuritis (for example, a lesion at the elbow) there is no flattening of the thenar eminence except in a few rare cases of ulnar innervation of the thenar muscles (Highet, 1943), there is no shoulder pain, the lesion is strictly confined to ulnar territory, and relief does not follow abduction of the limb.

Cervical Disk Lesions.—In cervical disk lesions the disk involved is usually that between C5 and C6 or that between C6 or C7, so that the root affected is either C6 or C7. Pain is more intense in the shoulder region; ulnar-sided pain or tingling is not present in the forearm or in the hand, and symptoms usually appear at a later age. Radiology may show a narrowed disk space between the vertebrae. Elevating the head—pressing upwards below the mastoids—may relieve the pain during an attack, and further differentiation may be provided by the abduction test.

Writers' Cramp.—This has a hysterical background which is often elicited on cross-examination—e.g., it occurs only when writing Service or business letters and not when writing for pleasure, and there is an absence of the precise mechanical picture presented by the patient with a scalene syndrome.

The Abduction Test.—If the signs and symptoms are due to the scalene syndrome or a cervical rib they are produced by a chafing action of the lowest trunk of the brachial plexus over the rib or the band representing it. If the nerve trunk is therefore lifted off the rib or band and kept thus elevated, the condition is alleviated. This may be achieved by placing the arm at rest in abduction on an aeroplane splint and so maintaining it for a few days.

Treatment

Non-operative.—In early and mild cases relief may be obtained by splinting and rest followed by exercises designed to develop the elevating musculature of the shoulder girdle In more persistent cases, in which the abduction test has confirmed the presence of a chafing structure below the lowest trunk of the brachial plexus, operation is indicated

Operative.—This consists of exploration of the region of the lowest components of the brachial plexus and also the subclavian artery in its three parts. A straight incision running upwards and outwards across the root of the neck in a crease-line just above the clavicle gives adequate access If care is taken to free completely the artery from compression and the lower side of the nerve trunk from chafing or other irritation, the results of operation are excellent

Comment

The views here expressed are derived from my experience of 33 operations which in the past twelve years I have performed for the scalene syndrome or costoclavicular compression. Eight operations were performed for cervical rib, 25 for the scalene syndrome. These 33 operations represent 30 patients. Bilateral operations were performed in two—in the one case separated by an interval of four months, in the other by one of 11 years. These were both cases of scalene syndrome in which a second operation on the other side was requested because of the benefit obtained from the first operation. In another case I performed two operations on the same side because of a return of symptoms due to adhesions. Three other patients had been operated upon previously by other surgeons. In one a cervical rib had been removed on the left side, and as similar symptoms occurred on the opposite side she requested removal of the rib on that side also: the other two cases were recurrences due to the lower side of the lowest trunk of the plexus not having been freed from its source of irritation. Of my 30 patients, 17 were women, 13 men; their ages varied between 17 and 55. One patient, a man of 45, was in jeopardy with gangrene of his fingertips and a subclavian aneurysm due to the artery being damaged by costoclavicular compression. I resected the aneurysm and left the rib. He has been well and doing hard work in a motor garage for nine years since the operation.

Conclusion

The scalene syndrome is of commoner occurrence than cervical rib in producing pain in the upper limb, and when symptoms are persistent it is not enough merely to divide the scalenus anticus, because the lowest trunk of the brachial plexus may still be stretched over and from time to time chafed by an underlying rib or band, or by the medial and tendinous lower fibres of the scalenus medius or an abnormal scalene muscle. It is necessary to divide any such structure so as to free completely the lowest trunk of the plexus, exploration of which is therefore the indication and not merely anterior scalenotomy. Similarly, where the subclavian artery is elevated over and compressed between an abnormal rib behind and the scalenus anticus in front, the part of the abnormal rib lying below and behind the artery must be removed so that the vessel is free to sink down on to Sibson's fascia. Only if these principles are applied in operating on cases of pain in the upper limb due to lesions of the thoracic operculum may we expect results that are wholly satisfactory.

Summary

Pain in the upper limb due to lesions of the upper thoracic opening may be the result of compression of the subclavian artery (the costoclavicular syndrome), or irritation by a band, rib, the scalenus medius, or an abnormal scalene muscle of the lowest trunk of the brachial plexus stretched over it and compressed from in front by the scalenus anticus (the scalene syndrome).

Similar pain does not occur in the lower limb, because acute angulation of the nerve trunks leaving the pelvis does not occur as in the case of the neurovascular bundle leaving the thorax. This angulation in the case of the upper limb and its absence in the case of the lower limb is due to the upright posture.

Elevation of the limb to a right-angle will usually relieve symptoms, indicating that similar relief can be obtained from operation.

Operation is best performed through an incision above the clavicle crossing the posterior triangle of the neck.

Anterior scalenotomy is not enough. The under surface of the lowest trunk of the plexus must be cleared so that no further chafing action of this nerve trunk can occur.

I am indebted to my friend and colleague Mr. Cecil Lewis, F.R.C.S., for the accompanying drawings.

THE COMPARATIVE MERITS OF SODIUM AND PROCAINE PENICILLIN GIVEN INFREQUENTLY

BY

E. GRIFFITHS, F.R.C.S.
P. F. JONES, F.R.C.S.
Surgical Professorial Unit, St. Bartholomew's Hospital
R. A. SHOOTER, M.D.
Department of Bacteriology, St. Bartholomew's Hospital
AND
J. A. HEADY, M.A.
Department of Statistics, St. Bartholomew's Hospital

Penicillin is widely used in general practice and in the out-patient departments of hospitals for the treatment of acute staphylococcal infections of the skin and subcutaneous tissues, but as yet the dosage employed in different hospitals varies widely.

One school, of which the chief protagonist has been Eagle, believes that the aim should be to maintain a bactericidal level of penicillin in the blood, and hence in the tissues, continuously throughout treatment. This belief is based (Eagle, 1948) on the principle that the frequency of penicillin administration should depend on the generation-time of the micro-organism concerned. If too long a period after administration is allowed the blood will become free from penicillin and surviving organisms will be able to multiply. If this is permitted for only a brief period the effect of treatment will merely be counteracted in part; if, however, too long an interval is allowed the effect of treatment may be counteracted by the supervening multiplication of organisms. This view receives tacit support from the fairly general practice of treating out-patients with large doses of penicillin once or twice a day, and admitting to the wards serious cases, or those which do not improve, for treatment with three-hourly injections.

On the other hand, clinical reports in ever-increasing numbers suggest that penicillin given in large doses daily or twice daily is effective for staphylococcal infections.

For instance, Wheatley (1947) treated seven cases successfully, in six of which single daily doses of not more than 200,000 units of penicillin were employed. D'Abreu, Flood, and Hewitt (1947) and Barclay (1949) report some benefit from the use of spaced doses in the treatment of septic hands, although in the last group systemic penicillin was combined with local penicillin.

The object of this paper is to describe a clinical investigation in which acute septic infections of the skin and subcutaneous tissues, mainly staphylococcal, have been treated by one of two methods, the first designed to keep a low penicillin concentration in the blood throughout most of the 24 hours, the second to produce two high concentrations of penicillin in the 24 hours, allowing the blood to become free from penicillin during an appreciable part of that period. The opportunity has also been taken to make some general observations on the treatment of infections of this type.

Methods of Treatment

The first group of patients was given a single daily intramuscular injection of 300,000 units of procaine penicillin in arachis oil, an amount which has been shown to produce low concentrations throughout most of a 24-hour period

---

The Scottish Society of the History of Medicine, which was founded in April, 1948, has just issued its first annual report. There are already 75 members of the Society, and it is hoped that this number will increase. The sixth meeting, and the first annual meeting of the society, was held in the council room of the University of Edinburgh on October 1, 1949. It took the form of a discussion on "The Teaching of the History of Medicine." The subject was introduced by the president, Dr. Douglas Guthrie, followed by Dr. W. D. D. Small, P.R.C.P.Ed., and Mr. Denys Hay, lecturer on history and director of studies in the Faculty of Arts. A large number of members took part in the discussion, and the honorary secretary, Dr. H. P. Tait, brought the meeting to an end with a brief review of the opinions which had been expressed.

in the majority of patients (Jones and Shooter, 1948): the second group received two intramuscular injections of 300,000 units of sodium penicillin in saline in the day. In the latter method penicillin was given when the patient was first seen, and subsequently between 9 and 10 o'clock in the morning and at 5 o'clock in the afternoon. In this way two high penicillin levels were produced each day and there was a total period of 8 to 14 hours in which no penicillin would be detectable in the blood. Both forms of treatment were continued for five days. In a small number of cases the treatment was continued for a few extra days.

A smaller group of patients, not included in the main series, was treated with 300,000 units of procaine penicillin in arachis oil with 2% aluminium stearate. These injections were given once every two days.

As local treatment, sodium sulphate (12½%) dressings and, in some cases, kaolin poultices were used, and immobilization of the affected part was advised. Lesions were incised only when necessary, with minimal incision. Boils and carbuncles were never so treated. In general it can be said that the local treatment in the two series followed exactly the same lines, without reference to the type of penicillin used.

All the patients were seen by one of us (E.G. or P.F.J.), usually at daily intervals, and never less frequently than once in three days. Clinical findings were recorded on a special form. As a rule swabs were taken from lesions before beginning treatment, but when the lesion was not open at the start it was swabbed as soon as possible after it had begun to discharge. Subsequent swabs were taken at five-day intervals until the lesions healed.

Conditions Treated

The patients treated were those attending the out-patient department of the hospital suffering from acute staphylococcal infections of the skin and subcutaneous tissues who required penicillin for treatment. Patients attending during the first month were allotted to the procaine penicillin series and those in the next month to the saline penicillin series, and this alternation was continued throughout the trial. In view of the ample evidence of the value of penicillin in the treatment of staphylococcal infections it was not considered justifiable to deprive patients of the antibiotic in order to provide a control series.

The types of infection treated are given in Table I.

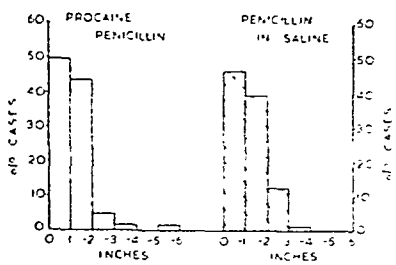

TABLE I.—*Types of Infection Treated (116 Patients in Each Group)*

Condition	Procaine Penicillin	Saline Penicillin	Total
Boils	32	23	55
Cellulitis	15	13	28
All carbuncles except dorsal finger carbuncles	23	25	48
Dorsal finger carbuncles	6	8	14
Other conditions	40	47	87
Total infections	116	116	232

Patients who took their discharge while under treatment were not included in either series; neither were those patients with infected burns, chronic osteomyelitis, and hand infections (other than dorsal finger carbuncles) who were treated with penicillin while this trial was in progress. The final category in Table I, "other conditions," included those lesions which were not numerous enough to form separate groups, and comprised such conditions as lymphadenitis, abscesses, and erysipelas.

Comparison of Lesions in the Two Groups

Dealing with such a heterogeneous collection of infections, it has been difficult to ensure that the two series of cases were comparable, and some lesions were included in one series which had no strict parallel in the other. In an attempt to compare lesions in the two series the approximate diameter or greater transverse measurement of the area of redness and induration was recorded. These findings, together with the time interval between the patient's noticing any abnormality and his attendance for treatment (time to treatment), are given in Table II. Fig. 1 shows diagrammatically the extent of induration. All three findings were not always recorded for each patient. In the table the means are based only on the patients for whom the findings were recorded.

EXTENT OF INDURATION

FIG. 1

TABLE II

	Mean Time to Treatment (Days)		Mean Redness (in.)		Mean Induration (in.)	
	Procaine Penicillin	Saline Penicillin	Procaine Penicillin	Saline Penicillin	Procaine Penicillin	Saline Penicillin
Boils	3·5	3·7	1·5	1·3	1·1	1·1
Cellulitis	6·7	4·1	2·6	2·9	1·3	1·6
Carbuncles of neck	7·1	7·9	1·7*	2·5	2·0*	2·1
All carbuncles except dorsal finger carbuncles	5·8	5·3	1·8	2·5	1·7	1·9
Dorsal finger carbuncles	6·0	3·9	1·8	1·7	1·2	1·0
Other conditions	4·8	4·6	2·1	2·1	1·6	1·4
All conditions	4·9	4·5	1·9	2·1	1·4	1·4

* *The apparent inconsistency shown here is due to the fact that for one patient with a large indurated area the redness was not recorded.*

Results of Treatment

As a criterion of the results of treatment, the time between onset of treatment and the relief of pain, and the healing time, which was defined as the time from the start of treatment to epithelization, have been taken. These times are given in Table III and diagrammatically for the individual groups of lesions in Fig. 2. Information was not recorded in every case, and the figures in parentheses indicate the number of cases on which the mean times were

TABLE III

	Mean Time to Relief of Pain (Hours)			Mean Healing Time (Days)		
	Procaine Penicillin	Saline Penicillin	All Cases	Procaine Penicillin	Saline Penicillin	All Cases
Boils	28 (19)	24 (17)	26 (36)	8·2 (29)	7·9 (21)	8·0 (50)
Cellulitis	35 (5)	24 (10)	27 (15)	8·4 (15)	7·3 (12)	7·9 (27)
Carbuncles of neck	—	39 (6)	38 (10)	13·1 (10)	12·3 (7)	12·8 (17)
All carbuncles except dorsal finger carbuncles	35 (9)	27 (22)	29 (31)	14·7 (22)	11·9 (23)	13·2 (45)
Dorsal finger carbuncles	28 (5)	19 (7)	23 (12)	12·0 (5)	12·3 (8)	12·2 (13)
Other conditions	28 (19)	27 (35)	27 (54)	8·9 (38)	7·5 (45)	8·1 (83)
All conditions	29 (57)	26 (91)	27 (148)	10·0 (109)	8·8 (109)	9·4 (218)

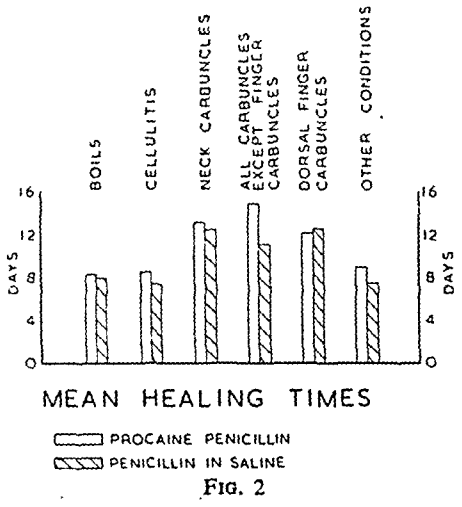

FIG. 2

based. Where this number was less than five no entry was made in the table.

There was an indication that the longer the period before the patient attended for treatment the longer was the healing time. Table IV gives the mean healing times for both series together, corresponding with days before patients sought treatment, where this information was recorded.

Two groups of lesions which responded similarly in both series merit further comment.

TABLE IV

Mean Time to Treatment (Days)	Number in Group	Mean Healing Time (Days)
−1	14	5·4
−2	43	7·6
−3	35	9·5
−4	22	10·2
−5	22	9·5
−6	16	9·8
−7	15	12·9
−14	20	13·0
14+	1	14·0

The correlation coefficient between mean time to treatment and mean healing time is 0·27, which is significant ($p < 0·05$).

Carbuncles

These have been among the most satisfactory infections to treat. In all cases treatment has been entirely conservative, and the relief of pain and toxaemia has been remarkable. Usually within two days, sometimes within hours, the surrounding area of redness disappeared and the induration softened. Finally, with separation of the slough the lesion was left as an area of healthy granulation tissue, with no reaction in the surrounding skin or connective tissue. Some carbuncles responded with exceptional speed and seemed to be completely absorbed, without slough formation. No complications of any kind were seen in this series.

Dorsal Finger Carbuncles.—The importance of the dorsum of the proximal phalanx as a site for carbuncular lesions seems to be insufficiently recognized. Donald (1948) and Pilcher *et al.* (1948) are among the few authors who specifically mention these lesions, which, we have found, are generally diagnosed as boils and sometimes treated by incision, with disappointing results. If not treated with penicillin they tend to pursue a chronic course and are apt to give rise to complications such as osteomyelitis, stiff finger, and tender scar (Pilcher *et al.*, 1948). No complications followed in the 14 cases treated.

Cases Treated with Procaine Penicillin and Aluminium Stearate

A small group of 24 patients was treated with 300,000 units of procaine penicillin in arachis oil with 2% aluminium stearate, this amount being given when the patient was first seen and repeated every two days. The infections treated comprised boils, carbuncles, and abscesses. Although in 22 of the patients amounts of penicillin which could be assayed were present in the blood towards the end of the first 24 hours of treatment, and in the blood of 10 of the 11 patients tested towards the end of the second 24 hours, the clinical response was unsatisfactory. After six of the 24 patients had been transferred to treatment with procaine penicillin with successful results no further patients were treated with procaine penicillin containing 2% aluminium stearate.

Bacteriology

All the swabs were sown direct on to horse-blood agar plates from which two cups had been cut with a cork-borer. After inoculation the cups were filled with 1 unit per ml. and 10 units per ml. of penicillin respectively. Staphylococci which after subculture from the primary plate coagulated plasma in a tube were described as *Staphylococcus pyogenes*. Penicillinase production was noted from the primary plate by the method described by Waterworth (1948).

The results of the swab examinations when organisms were grown are given in Table V.

TABLE V

Organisms Isolated from Initial Swabs	Cases
Staph. pyogenes, penicillin-sensitive	180
Staph. pyogenes, penicillin-resistant	13
Gram-negative bacilli	8
Haemolytic streptococci	11

Of the eight Gram-negative bacilli isolated, two proved to be *Proteus* and one *Ps. fluorescens*; six were not identified. Of the 11 haemolytic streptococci, only two occurred in the absence of *Staph. pyogenes*.

A further 231 swabs were examined from patients during the course of treatment, and four more Gram-negative bacilli were recovered which were not present in the initial swabs. One of these was *Proteus* and one *Bact. coli* (intermediate type II); two were not identified. From only one of these subsequent swabs were haemolytic streptococci isolated when they had been absent originally.

General Observations on Treatment

During the course of this investigation it was our impression that the cases in the two series were responding in much the same way, and this has been confirmed by statistical analysis, there being no significant difference between any of the groups in either series. The two series were tested for differences in mean (t) and differences in distribution (χ^2) in all groups. The apparent consistency with which the healing times for the saline penicillin series were shorter than the healing times for the procaine penicillin series, shown in Table III, was also shown not to be significant.

Three observations were made which had no bearing on the main course of the investigation, as the facts observed occurred in both series. The first was that when the pain was relieved it sometimes went very quickly—at one moment it was there and within half an hour it had almost entirely gone. The second observation was that in many cases the original purulent lesion was replaced by apparently healthy granulation tissue in a fairly short time, and it took as long again for this comparatively small area to be covered by epithelium. This was particularly noted in the boils and carbuncles, and accounted for a considerable part of the healing time.

Thirdly, it was interesting that in some of the lesions coagulase-positive staphylococci could be demonstrated

before and during treatment, persisting until the lesion healed; this persistence apparently did not influence clinical recovery.

Discussion

Judged by the results obtained in the two main series of cases it would appear that an equally satisfactory response can be obtained in the treatment of out-patients by the use of either daily injections of 300,000 units of procaine penicillin in arachis oil or twice-daily injections of 300,000 units of penicillin in saline. It would therefore seem that for treatment of infections of the kind described a continuous bactericidal level of penicillin in the blood is not necessary.

Our experience of the use of 300,000 units of procaine penicillin with 2% aluminium stearate was not extensive, but it appeared that while clinical improvement took place it did not occur as rapidly as in the patients treated with procaine penicillin or with penicillin in saline. This suggested that persistence in the blood had been obtained at the expense of adequate blood concentration. The preparation containing aluminium stearate may well provide excellent treatment for infections caused by more sensitive organisms than staphylococci, but for the treatment of staphylococcus infections there would seem to be a place for a preparation of procaine penicillin, with or without aluminium stearate, which also incorporated crystalline penicillin to provide a high initial blood concentration.

The number of cases with resistant staphylococci was too small to allow of their being placed in a separate group, and, although it would have been highly desirable, no comment can be made on the response of such cases to treatment with penicillin. At present the number of infections in out-patients due to penicillin-resistant staphylococci is small, but in view of the growing number of reports of the increasing proportion of resistant strains in hospital wards it is likely that these infections may in time present a serious problem.

The number of lesions in which Gram-negative bacilli were present was also small, and there was no evidence in this series of cases that infection with Gram-negative bacilli played any major part in delaying healing.

Summary

The results of a clinical investigation are presented in which 116 patients with acute septic infections of the skin and subcutaneous tissues, mainly staphylococcal, were treated with daily injections of 300,000 units of procaine penicillin and a similar number of patients were treated with twice-daily injections of 300,000 units of penicillin in saline.

No significant difference between the response to treatment of these two groups was detected.

We would like to thank Professor Sir James Paterson Ross and Professor L. P. Garrod for the advice and encouragement they have given us; Miss Deal, sister in charge of the surgery, and the nursing staff for their co-operation; and Miss M. Rhodes and Mr. R. Andrew for technical assistance. The procaine penicillin used was supplied by Messrs. Glaxo Laboratories, to whom we are indebted for the supply of procaine penicillin with 2% aluminium stearate.

"NEO-EPININE" IN THE DYSPNOEA OF COAL-MINERS

BY

C. KELMAN ROBERTSON, M.D., D.P.H., F.R.C.P.Ed.

Assistant Physician, Royal Infirmary, Edinburgh

The most outstanding symptom of the pneumoconiosis of coal-miners is dyspnoea. This symptom occurs in mild degree in the earliest stages of the disease, but progresses over a period of years to such an extent that it may wholly incapacitate. In the advanced stages of anthracosilicosis gross pulmonary fibrotic changes have taken place, and in order to compensate for such loss of healthy functioning lung tissue respiration is speeded up and therefore dyspnoea becomes marked. In the beginning, however, the breathlessness is more difficult to explain. It could be attributed to various factors such as early bronchitis, focal emphysema, the psychic outlook of the patient, or a possible bronchospasmodic effect of siliceous matter.

As it was considered probable that some of the dyspnoea might be due to bronchospasm, alone or associated with emphysema, it was decided to try the effect of the most potent modern bronchodilator available.

Konzett in 1940 described the pharmacological actions of homologues of adrenaline and noted that the isopropyl derivative had a powerful relaxing effect on bronchial muscle spasm. The relaxant power of this derivative was considered to be 10 times stronger than that of the parent substance adrenaline. Little or no clinical application of this knowledge was made in this country until last year, when Herxheimer (1948) recorded his favourable findings with "aleudrine" (isopropyl adrenaline) in cases of asthma, although satisfactory reports had been forthcoming in the intervening years from the Continent (Stolzenberger-Seidel, 1940; Quitschal, 1942) and the United States (Segal and Beakey, 1947: Charlier, 1947).

Present Investigation

In order to assess the merits of such a bronchodilator in this disease 58 colliers, all complaining of shortness of breath in some degree or other, were investigated. The preparation used in the experiment was isopropyl-noradrenaline sulphate, "neo-epinine" (Burroughs Wellcome and Co.), which is chemically *dl*-α-3 : 4-dihydroxyphenyl-β-isopropylaminoethanol sulphate, and which is known to have the therapeutic quality of enhancing vital capacity. The neo-epinine had for convenience to be used in tablet form, each tablet containing 20 mg. of the drug. Strict instructions were given regarding slow sublingual dissolution and the swallowing of as little saliva as possible. Inert tablets of exactly identical appearance were also supplied by Messrs. Burroughs Wellcome and were used in all cases for the first week of treatment and when it was thought that functional factors were clouding the issue.

Type of Case.—No special attempt was made to select any particular type of anthracosilicotic so far as age-grouping, radiographical grading, length of time in mines, etc., were concerned. The youngest man was 33 years old, the oldest 65, and the average age for the whole group 56.3 years. Radiographical grading, international classification (International Labour Office Studies and Reports, 1930), was: 29 showing partial distribution of linear shadowing and an early indication of nodulation (Ia), five more widespread shadowing (Ib), five generalized but still

discrete nodulation (Ic), and five increase in number and size of discrete shadows with a tendency to confluence (II). Those that could not be classified according to this standard were regarded as: emphysema, five; bronchitis, five; and negative, four. If, however, cardio-renal disease was thought to play any part in the development of the dyspnoea, then such patients were considered to be unsuitable for investigation. The criteria for the test were simply (1) that the man was or had been working in the coal-mines for many years, and (2) that his main complaint was shortness of breath which could be attributed to his work, no other cause being found.

Routine Adopted

At the first visit of the patient to hospital the following details were recorded: (*a*) careful medical and occupational history; (*b*) clinical examination; (*c*) urinanalysis; (*d*) Hb percentage, leucocyte count, erythrocyte sedimentation rate, sputum examination, blood urea, and electrocardiography if considered necessary; (*e*) vital capacity estimation; (*f*) *x*-ray examination.

It was at this time explained to the man that as his chief complaint was shortness of breath we were going to try to improve this by means of tablets, but that we would need his careful co-operation and he would be required to report back to hospital each week for a period of five or six weeks so that we might assess his progress. He was then given a seven-days supply of inert tablets, being told to take one three times a day, with the already noted injunction about slow sublingual melting. On the succeeding visits the patients were given a weekly supply of neo-epinine after the vital capacity had been recorded. It was considered that the study of the vital capacity would be the most valuable estimate of the effect of the drug. Especial care was taken on all occasions to allow each man plenty of time to explain exactly how he felt and what effect, if any, the new drug had on his breathing and general feeling of well-being.

Results

It was found, during the test period when the patients were having the inert tablets, that there was on the average a slight increase in the vital capacity but not such as could not be ruled out by experimental error. With neo-epinine, however, there was an actual average increase of 236 ml. Irrespective of vital-capacity estimations, the comments of the patients were interesting, as 44 admitted improvement, 11 considered that their condition was unchanged, and one said that he felt worse; two did not complete the test. The 44 who felt better were further classified according to their expressions of well-being: 17 were enthusiastic about the effect of treatment, another 17 said they were better but thought that they could still make more of it, while the remaining 10 thought that they had improved a little, though they still complained of symptoms such as shortness of breath on hurrying, ascending hills, etc.

As was to be expected, the commonest side-effect complained of with neo-epinine was palpitation; this, however, was always a transient feature, lasting only a matter of 10 to 15 minutes after taking the tablets. Other passing complaints were shakiness, giddiness, and flushing.

The inert tablets did not give rise to any untoward symptoms. It has to be noted that no attempt was made to vary the dose of the drug according to the severity of the dyspnoea, and whether or not any degree of tolerance arises with the use of this drug in such cases cannot at present be stated.

Summary

On the assumption that dyspnoea in the earliest stages of pneumoconiosis might be due to bronchospasm associated with focal emphysema it was considered desirable to try the effect of a bronchodilator. It was thought that the iso-propyl derivative of adrenaline, a powerful bronchial antispasmodic, might prove useful in these cases.

Fifty-eight colliers complaining of breathlessness were given inert tablets for one week, followed by *neo-epinine* tablets for four weeks. It was found that there was little or no difference in vital-capacity estimations with the inert tablets, but after *neo-epinine* had been taken for four weeks there was an average increase of 236 ml.

Forty-four of the men commented upon a feeling of improvement in varying degree while under treatment. Although there was an average increase in the vital capacity with this drug, it is realized that some of the improvement could be "spiritual," as in Fletcher's (1948) classic description of such cases.

Toxic effects of the drug are noted.

I am indebted to Dr. A. Fergus Hewat for kind co-operation and permission to establish an out-patient pneumoconiosis clinic attached to his wards; also to Professor D. M. Lyon for much helpful criticism of this paper.

RECTAL HAEMORRHAGE ASSOCIATED WITH INFECTIOUS MONONUCLEOSIS

BY

P. ECKSTEIN, M.D., B.Chir.

AND

A. L. P. PEENEY, M.R.C.S., L.R.C.P.

(From the Department of Anatomy, Medical School, and Department of Clinical Pathology, Queen Elizabeth Hospital, Birmingham)

Rectal bleeding in the course of glandular fever is so rare an occurrence as to warrant a brief description.

Case Report

The patient, a man aged 34, gave no relevant previous history and had never manifested any haemorrhagic tendencies. He suffered a typical mild attack of glandular fever during which there was no jaundice or severe malaise and the temperature did not exceed 100° F. (37.8° C.) at any time. Generalized lymphadenopathy affecting the glands of the neck, axillae, and groins was first noticed on the fifth day, following an ill-defined influenza-like onset. On that day the patient sought medical advice at hospital, where a palpable spleen was found and the clinical diagnosis of infectious mononucleosis confirmed by a blood examination (see Table).

Subsequently the patient seemed to make a satisfactory recovery, becoming completely apyrexial on the seventh day and getting up for a short period during the ninth. However, later in the evening of that day, while micturating, he passed some bright, partly clotted blood per rectum. The bleeding was not profuse and could be stopped by rest, but it was immediately brought on again by straining such as passing urine or flatus. This condition persisted during the night and the following morning (the tenth day), when the patient presented

Laboratory Findings

	Day of Disease				2 Months after Clinical Recovery (55th Day)
	5th	10th	14th	23rd

himself at hospital and was admitted at once. An immediate sigmoidoscopy merely confirmed the occurrence of active bleeding from above the pile-bearing area of the rectum, but failed to locate an actual bleeding site.

Treatment was conservative and consisted of complete rest in bed, a strict ulcer diet, and 10 mg. of vitamin K three times a day. During the night following admission one motion consisting almost entirely of clotted blood was passed. From then onwards active bleeding stopped. Altered blood in diminishing quantities was present for two more days, after which the faeces became normal and clinical progress was rapid. It is estimated that the total blood loss sustained during the 36 hours of active though intermittent bleeding amounted to at least ½ pint (284 ml.).

On the fifteenth day sigmoidoscopy was repeated after proper medical preparation. The instrument was passed to 1 in. (2.5 cm.) beyond the pelvi-rectal junction, where faecal matter was encountered. A thorough search failed to show any abnormality of the rectum. Finally, a full radiological examination of the alimentary canal, including barium enema and "follow-through," was carried out, again without revealing any pathological condition.

The patient was discharged on the twenty-second day after the onset of symptoms. At that time the enlargement of the lymph glands and spleen had almost completely subsided. There has since been no recurrence of the bleeding, and the patient has remained well up to the time of writing—a period of over twelve months.

Discussion

Haemorrhagic manifestations varying from epistaxis to purpuric lesions are well recognized among the rarer complications of infectious mononucleosis (Tidy and Morley, 1921; Downey and McKinlay, 1923; Bernstein, 1940). However, rectal bleeding seems to be almost unknown. It is not mentioned in any of the current textbooks or in recent reviews (e.g., Contratto, 1944; Bethell, Sturgis, Rundles, and Meyers, 1946; Gardner and Paul, 1947). Only two instances were found in the literature. In 1934 Tidy made reference to the occurrence of "rectal haemorrhage with bright blood in a child" without giving any further details. Israëls (1937) reported recovery from a "single quite considerable haemorrhage from the rectum after defaecation" in a woman aged 21, but this particular case presented various unusual features and was further complicated by the fact that the patient was known to possess a definite bleeding tendency.

The association of rectal haemorrhage with the attack of glandular fever here recorded is suggestive though not conclusive, and no claim can be made that a definite causal relationship between them has been established. On the other hand, the patient gave no history of a haemorrhagic diathesis and has shown no signs of a recurrence since his recovery. Unfortunately, the bleeding and clotting times were not determined, but clinically there was no evidence of purpura, and the normal prothrombin and platelet findings go far to rule out the existence of a bleeding state. A very thorough search for alternative and more usual causes of intestinal haemorrhage was made by means of the sigmoidoscope and radiographs; there can be few pathological conditions (with the possible exception of a minute haemangioma or telangiectatic focus) that would escape detection when so investigated. There was no personal or family history of telangiectasis. Other rare factors like congenital diverticula can probably be excluded in view of the patient's age.

Summary

The occurrence of rectal haemorrhage during a mild bout of infectious mononucleosis was observed in a man aged 34.

The bleeding resulted in a loss of over half a pint of blood and was not accompanied by significant thrombocytopenia or hypoprothrombinaemia. Thorough investigation of the alimentary canal by sigmoidoscopy and radiographs revealed no pathological condition which might have accounted for the haemorrhage. Recovery was apparently complete, and there has been no recurrence of the bleeding for a period of more than twelve months.

We wish to thank Mr. B. N. Brooke, of the Department of Surgery, Queen Elizabeth Hospital, for his permission to publish this account and for access to the case notes.

DISSECTING ANEURYSM OF THE AORTA SIMULATING EMBOLISM AT THE AORTIC BIFURCATION

BY

H. S. SHUCKSMITH, B.Sc., M.B., F.R.C.S.
Assistant Surgeon, the General Infirmary at Leeds

AND

I. MACPHERSON, M.D., M.R.C.P.
Assistant Physician, the General Infirmary at Leeds

The details of a fatal case of a dissecting aneurysm of the aorta are here recorded. At one stage an embolus near the aortic bifurcation was suspected, and during a phase of recovery coldness of the skin over an area proximal to the ankles persisted longer than coldness of the feet.

Case Report

A man aged 66 who had had a coronary thrombosis 15 years previously was seized with an agonizing pain round the upper abdomen and also low down in the back while chasing cattle. An hour later a severe pain developed in the left thigh and calf, followed in half an hour by similar pain in the right limb. He collapsed and could neither feel nor move his legs. Four hours after the onset of the illness the pulse was regular, the

blood pressure was 130/100 mm. Hg, and auscultation of the heart did not reveal any abnormality.

Left Lower Limb.—The colour was normal, active movement was present only in the left great toe, the left common femoral pulse was present though small in volume, but the posterior tibial and dorsalis pedis pulses were absent. The skin was anaesthetic as far up as the lower abdomen and was cold from the knee downwards. The knee and ankle reflexes were absent.

Right Lower Limb.—The leg was pale from the knee downwards; there were no active movements and the common femoral pulse was absent. The skin was anaesthetic as far up as the middle third of the thigh and was cold from the knee downwards. The reflexes were absent.

Five hours after the onset of the illness there was no change in the right limb, while in the left full movement had returned and the only abnormalities were absence of the posterior tibial and dorsalis pedis pulses and coldness of the skin below the mid-shin, including the foot. Two hours later the skin above the left ankle was still cold, while the thigh and foot were warm. There had been full recovery of movement in the right limb, and the common femoral pulse was now present and was larger in volume than the left; coldness was found on the dorsum of the foot and as far as the knee, while the toes were warm. Oscillometer readings were as follows:

	Thigh		Calf	
	Right	Left	Right	Left
180 mm. Hg	3½	1	2½	½
160 „ „	5	1	4	½
140 „ „	5½	1½	5	½
120 „ „	5	2	6	½
100 „ „	4½	1½	6	1½
80 „ „	3	1	5	1½

The areas of coldness showed no further change until 14 hours after the onset, when the whole of the right foot was warm, but coldness of the skin above each ankle remained for several hours longer.

The following day the limbs were normal except for the difference in common femoral pulsation. The blood pressure had risen to 260/140, but the patient was cyanosed and breathless, and he died 48 hours after the onset of the illness.

Limited Necropsy.—A dissecting aneurysm started in the first part of the aorta, involved the abdominal aorta, and extended as far down as the middle of the right common iliac artery. There was a large atheromatous plaque in the right common iliac artery at the same level as the lower margin of the extravasated blood. The left common iliac artery was normal. The dissecting aneurysm extended about one-third of the way round the ascending part of the aorta and a quarter of the way round the right common iliac artery. There was a large collection of blood in the pericardium and of blood-stained fluid in the left pleura.

A large fibrotic area was present in the mid-posterior zone of the heart, due to an old coronary thrombosis, and there was advanced coronary atheroma, particularly of the anterior descending branch. No evidence of a recent infarct was found. The middle of the aorta and the femoral arteries were not examined.

Discussion

The difficulty in diagnosis of the vascular cause of sudden pain and paralysis in a limb is the element of arterial spasm which may occur both in embolus and in dissecting aneurysm; a dissecting aneurysm may also directly interfere with the blood supply of the spinal cord. The only constant findings in embolus are absence of the peripheral pulse, lowered surface temperature, and pallor (Allen, Barker, and Hines, 1946). The initial physical signs suggested an embolus completely blocking the right common iliac artery and partially blocking the left, but the fact that symptoms on the left preceded those on the right by half an hour made this unlikely, and rapid and marked improvement of the condition of the limbs finally excluded embolus and ischaemia of the cord.

The changes in the surface temperatures over different parts of the lower limbs merit emphasis. In both limbs the last area of skin to warm up was not over the foot but over the area surrounding the leg just above the ankle. This area remained cold for some hours while the foot and calf were warm. Dr. John Homans told one of us (H.S.S.) that it was not uncommon after anaesthetizing the lumbar sympathetic ganglia to find the first area in the limb to warm up is behind and above the malleoli, a reaction which takes place well in advance of the temperature changes in the toes. The delayed vasodilatation in the area of skin proximal to the ankle in this case and the early vasodilatation in the same area following lumbar sympathetic block point to a peculiarity in the arteriolar pattern which may be related to the formation at this site of ulcers that are variously labelled varicose, post-phlebitic, or gravitational.

Summary

In a case of dissecting aneurysm of the aorta there was marked spasm of the lower limb arteries, with coldness and paralysis of the legs simulating embolism at the aortic bifurcation. In the recovery phase the last portion of the skin in each leg to become warm was a localized area of the skin just above the ankle. It is suggested that there may be an exceptional vascular arrangement at this site, possibly related to the occurrence of ulcers of the legs.

We are grateful to Dr. G. F. Fowler and Dr. C. V. Light for their help with this case.

Medical Memoranda

Case of Erysipeloid of Rosenbach Treated with Penicillin

Infection of human beings with *Erysipelothrix rhusiopathiae* is by no means common. It is, however, to illustrate the response of this infection to penicillin therapy that the following case is described. Few cases treated with penicillin have been recorded in this country; Barber, Nellen, and Zoob (1946) reported five cases, all of which responded well to penicillin. In America three cases have been reported (Ehrlich, 1946; Ferguson *et al.*, 1947; Stiles, 1947). All these cases showed a rapid response to penicillin. The progress of the disease untreated is slow and may be anything from one to five weeks, during which time complications may arise. Other treatment is of little or no value: the organism is not sensitive to sulphonamides, and serum therapy is uncertain and often gives rise to severe reactions.

Case Report

The patient, a man aged 34, is a veterinary surgeon engaged on research. Two days before attending he had been dissecting turkeys which had died of *Erysipelothrix rhusiopathiae* infections and from which the organisms had been cultured. During the dissection, not wearing gloves, he pricked himself on the left thumb. He presented with a typical lesion in that region. The skin over an area about 1 in. (2.5 cm.) in diameter was red, raised, and shiny, and the edge was sharply demarcated. Pruritus was marked and there was considerable pain and throbbing. Axillary adenitis was present, but there was no lymphangitis.

The arm was put in a sling and kaolin poultices were applied. Penicillin sodium, 100,000 units intramuscularly, was given twice daily. The improvement in 24 hours was marked, and in 48 hours the thumb appeared normal. The patient defaulted after five injections, however, and attended again two days later. The lesion then measured 2 by 1¼ in. (5 by 3.75 cm.): it was extremely painful and typical of the condition. Both lymphadenitis and lymphangitis were present.

Penicillin therapy was restarted, the dosage being increased to 250,000 units intramuscularly twice daily. In 48 hours there was a great improvement, and in 72 hours there was only a small area of erythema and no induration. Penicillin was continued for a further four days, after which the lesion had completely subsided.

Comment

The diagnosis was quite definite clinically in view of the history, the typical incubation period of two days, and the typical lesion. Demonstration of the organism requires biopsy, which was not considered justifiable. There were a dramatic response to penicillin, a rapid recurrence after inadequate therapy, and a further rapid response on restarting treatment. The appearance of the disease in turkeys is most unusual and has not been reported in this country before. The organism may therefore have been a particularly virulent one. It was shown, however, to be penicillin-sensitive on culture.

The case demonstrates a rapid response to penicillin in a case of erysipeloid, and the need for full doses of penicillin for an adequate period.

Imperforate Anus and Congenital Rectal Fistulae

Imperforate anus is said to occur once in every five or six thousand births; it is complicated by recto-urethral or recto-vaginal fistula about once in every 50,000 births.

Imperforate Anus

This condition may vary from a simple membranous occlusion to a large gap which it is difficult to bridge by surgery.

Case 1.—A male European child aged 12 hours was referred to me as a case of imperforate anus. On examination it was seen that although the anal depression was present the anal passage was not patent. A bulging membrane occluded the canal. This membrane was incised and faeces immediately poured out. Dilators were passed to complete the opening. This case was simply a failure of the anal membrane to disappear. It is probably the commonest form of imperforate anus and is certainly the simplest to relieve.

Case 2.—A female Tamil child aged 12 hours. The child had vomited, and the mother said there had been no bowel movement since birth. On examination there was a normal anus; the anal canal admitted a probe for a distance of half an inch (1.25 cm.) and was then stopped by a membrane. *Operation:*—An attempt was made to rupture the membrane with a myringotomy knife. No faeces appeared. A perineal opening was then made, but there was no sign of the rectum. A lower midline laparotomy was performed, and it was seen that the rectum ended at the upper end of the sacrum. There appeared to be no opening in the pelvic floor for the bowel. Working from above and below, a loop of sigmoid colon was brought through an opening made in the posterior pelvic floor. The loop of colon was opened and stitched to the dilated anal canal, the upper end of which had been cut to receive it. The abdominal incision was then closed. The child recovered without incident.

Imperforate Anus With Fistula Formation

Case 3.—A male Malay child aged one and half months. Since birth both urine and faeces were passed through an opening at the peno-scrotal junction. There was no sign of an anus. *Operation:*—A small probe was passed into the sinus. A midline perineal incision about 1 in. (2.5 cm.) long was then made back to the tip of the coccyx. This incision was deepened. By feeling for the probe the fistulous track was found and the rectum searched for. It was found to end about 1¼ in. (3.75 cm.) above the perineal skin surface and could not be drawn down. An opening was made in the lowest part of the rectum and a piece of soft rubber catheter tied in and brought through the perineal opening. The sinus was not ligated. Finally, a drain was put in just in front of the coccyx. The child passed a little faeces through the perineal drain for a few days, but this stopped and the fistula once again acted as a cloaca. It was decided to leave further attempts at closure until the child is old enough to stand the extensive procedures involved.

This case was due to failure of the urorectal septum to unite completely; the paramesonephric ducts were also involved. It is notable that the penile urethra was found to be patent. The case shows well the difficulty in treating high rectal occlusion. It would have been impossible even to open the rectum if the peritoneum had been traversed. A perineal anus could probably be made for this child at a later date by using pelvic colon, as it is unlikely that the rectum could be brought down. The remaining problem is that of sphincter function: should one make a perineal anus which may be uncontrollable?

Case 4.—A female Malay child of 5 months. Examination showed a perforate hymen and an opening in the posterior vaginal wall in the midline. Faeces were seen to come from this opening, and the mother stated this had been occurring since birth. *Operation:*—A midline perineal incision was made. The blind end of the rectum was found about ¾ in. (1.9 cm.) above the skin level. It was easily brought down and opened. The edges of the opening were stitched to the edges of the perineal incision. This child ceased to pass faeces into the vagina 48 hours after operation, although the fistula was not ligated.

The embryological fault here was an opening in the urorectal septum which also penetrated the paramesonephric ducts. This operation was completely successful, but as no evidence of a sphincter was seen it is doubtful if there will be a reasonable degree of control. According to Keith (1908) there is always an anal sphincter muscle present in cases of imperforate anus. This may be so, but it was not found in Cases 3 or 4, although it was present in Case 1. From the practical viewpoint it seems unlikely that there will be useful sphincteric action of the anus in the more severe degrees of maldevelopment. It is interesting to note that in neither of the cases with fistula was there any evidence of infection.

Keith, A. (1908). *British Medical Journal*, **1**, 1736.

In the 10-year period 1939–48 there were 12 cases of chronic benzene poisoning with 8 deaths, and 20 cases of toxic anaemia due to benzene with 5 deaths, reported to the Chief Inspector of Factories. Over the same period there were 519 gassing accidents with 31 deaths caused by substances in use as industrial solvents. These and other figures were discussed by Dr. A. J. Amor, president of the Association of Industrial Medical Officers, in a paper read at the Chemical Works Safety Conference which was held at Scarborough from October 7 to October 9. Other subjects discussed at the conference were the installation and maintenance of breathing apparatus and training in its use, and the types of electrical apparatus permissible for use in hazardous atmospheres.

Reviews

LIVER DISEASE

Diseases of the Liver, Gallbladder, and Bile Ducts. By S. S. Lichtman, M.D., F.A.C.P. 2nd ed. (Pp. 1,135; 147 illustrations and 2 plates in colour. £4 10s.) London: Henry Kimpton. 1949.

I confess to a weakness for medical monographs, and in this branch of literature the Americans have us beaten. These monographs are invaluable to the teacher of medicine and to the physician who wishes to expand his knowledge and take an intelligent interest in his cases. Samuel Johnson said, "A man may write at any time if he sets himself doggedly to do it," but how many potential authors would have sufficient doggedness to achieve a work of this character?

The first 120 pages of the book are concerned with the anatomy and physiology of the liver, and contain an interesting account of vitamin manufacture and storage in this organ. The author continues with a discussion of the pathogenesis and pathology of jaundice and the symptoms and signs of liver disease. That important and debatable subject, testing the liver function, occupies the next 113 pages. The usual objection put forward to these tests is that the reserve power of the liver is so great that four-fifths of its substance can be destroyed before any impairment of function is detectable. The author counters this and other criticisms, dismisses them, and emphasizes the importance of selecting suitable tests for the clinical problem in hand. In this chapter the reader who is not familiar with the subject will receive a good impression of the help to be obtained from properly selected tests in estimating the type and degree of liver damage, following the course of the disease, and estimating pre-operative risks.

The recent work on infective hepatitis is described in detail, and the mode of action of liver poisons is elucidated by an account of experiments involving nutritional deficiency and protective dietary factors. There is a good chapter on cirrhosis of the liver and the beneficial effects of high protein and high carbohydrate diets with methionine and vitamins A and B. These methods have improved the outlook in cases of cirrhosis accompanied by ascites. The reader will be able to familiarize himself with the various surgical procedures for the relief of portal hypertension and ascites, some of which involve the formation of portacaval venous shunts. In the last 100 pages is a discussion of the gall-bladder and bile ducts.

This book provides answers to most of our questions, although we may not necessarily agree with them. It is interesting to inquire what has happened to our old friends—catarrhal jaundice seems to be dead, although I am reluctant to believe the news; Hanot's cirrhosis still survives, despite the doubts cast on its existence by writers in this country during the last twenty years; xanthopsia is considered to be due to the presence of bile pigment in the ocular fluids when there is a high blood concentration. This does not accord with the clinical experience that xanthopsia very rarely occurs even in cases of intense jaundice, and that it is often transient, lasting only for a few minutes or less.

The book is well produced, the illustrations are of a high standard, and the text is documented by nearly 5,000 references. There is no sting in the tail of this review. I have nothing but praise for this excellent monograph.

G. E. Beaumont.

ALLERGY

Progress in Allergy. Edited by Paul Kallos. Volume 2. (Pp. 356; 50 figures. 36 Swiss francs.) Basle: S. Karger. 1949.

This book is an informative and stimulating symposium of recent work on allergy, and includes articles by many of the leading workers in the subject. Like its predecessor, published in 1939, it is edited by Paul Kallos. Some chapters are concerned with the practical aspects of clinical allergy, but the majority, including some of the best sections, are more academic studies dealing with antigen-antibody mechanisms and the pathogenesis of various allergic manifestations. Most of the articles are in English, but two, concerned with the pharmacology (Meier and Bucher) and the therapeutic value of antihistamine drugs (Kallos and Kallos-Deffner), are in German.

E. A. Kabat gives an excellent review of recent immunochemical work, including a description of the way in which this branch of biochemistry has been employed in the study of human viruses, in establishing the purity and homogeneity of antigens and antibodies, and in measuring antibody formation in response to bacterial and non-bacterial antigens. Professor Haxtausen contributes an illuminating chapter on allergy in diseases of the skin. He faces up to a number of incongruities which make it difficult to assess the importance of allergy in skin diseases. Thus it is well recognized that skin tests are of little value in urticaria, even when food sensitivity is suspected on clinical grounds, and this in spite of the fact that the reaction caused by percutaneous tests is identical with the naturally occurring eruption. It is suggested that this discrepancy may occur because the antigen is a breakdown product of digestion and not the unaltered food itself. Again, in Besnier's prurigo it is odd that percutaneous tests often give positive reactions of urticarial type, whereas patch tests with the same antigen are negative. The author suggests that the initial antigen-antibody reaction causes itching and that the characteristic eczematous lesions are secondary to the effect of scratching. Allergic eczema is fully discussed, including the formation of conjugated antigens, the effective stimulus to antibody formation, the possibility of localized sensitivity, and other aspects of its pathogenesis. Reference is also made to other allergic phenomena in various skin diseases and to the dermatological manifestations of drug-sensitivity. G. L. Waldbott writes on urticaria and F. A. Simon reviews the evidence in favour of sensitivity to human dander as a factor in the causation of infantile eczema.

Foster Kennedy discusses interestingly the subject of allergy in the central nervous system. He considers that localized areas of oedema in the brain may account for migraine, some cases of epilepsy, facial palsy (including ophthalmoplegia), and retrobulbar neuritis. He quotes a number of suggestive case histories, but more definite evidence is required before his views can be accepted. Other chapters are on allergic disease in animals, by F. W. Wittich, who first described hay-fever in dogs; allergy of the middle ear, by Hjalmar Koch; bronchoscopic therapy in asthma, by G. L. Waldbott; and aerosol therapy, by H. A. Abramson.

R. S. Bruce Pearson.

MEDICAL PROBLEMS OF FLYING

Aviation Medicine. By Kenneth G. Bergin, M.D., A.F.R.Ae.S. (Pp. 448; 120 illustrations. £1 15s.) Bristol: John Wright and Sons. 1949.

Aviation medicine covers a diverse and wide field: it ranges over nearly every branch of scientific medicine and draws on the physical and engineering sciences. The ramifications

are wide, and the rapidity with which the specialty has developed during the last decade has made it impossible for one author to deal with the whole subject. Dr. Bergin has, however, produced in readable and compact form a review of the physiological, medical, psychological, and epidemiological problems associated with present-day flying.

The book is a counterpart to the well-known U.S.A. publication by Armstrong and Heim, though this contained a considerable amount of original work, and it is the first of its kind to be published in this country. Its purpose is to provide the medical practitioner with information on the problems encountered in flying, which have become more numerous with developments in aircraft design resulting in increased speed, height, and engine power, and demanding a higher degree of endurance and a greater ability of judgment from aircrews. The author, himself a pilot of no mean attainment, presents his facts with that knowledge of aviation essential to those dealing with flying problems and personnel.

This work is a digest of the vast amount of research which was carried out in this country and in the U.S.A. during the war and contains a considerable amount of valuable information more applicable to Service than to civil flying. The author makes no claim to originality and he pays a handsome acknowledgment to those whose work he has consulted. The ample bibliography at the end of each chapter enhances the value of the book and provides the reader with the opportunity for a detailed study of the original contributions. The appendices contain useful data about medical requirements for licensing civilian pilots and the international health regulations for the prevention of epidemics.

While there is general agreement on the physical standards laid down, there is still some diversity of opinion on visual and hearing requirements: it is claimed that the experience of the individual should compensate for any physical defect. This opinion is not universally accepted, as it is liable to abuse. Furthermore, individual reactions and responses to identical defects are not always the same. Errors and risk of errors should be reduced to a minimum if the confidence of the public in aerial transport is to be maintained. The book should be in the hands of every medical practitioner called upon to express an opinion on the variety of problems encountered in aviation medicine. There are a few errors and omissions which doubtless will be corrected in the next edition.

E. D. Dalziel Dickson.

RENAL FUNCTION TESTS

Clearance Tests in Renal Disorders and Hypertension. By Olle Hogeman. Translated by Erica Odelberg. (Pp. 264. No price.) Sweden, Uppsala: Appelbergs Boktryckeri A.B. 1948.

Van Slyke, it has been said, first used the concept of renal clearance when seeking to dispense with mathematics for the benefit of the medical profession. The concept, whatever its humanitarian origin, gave a notable impetus to the advance in knowledge of renal function, an advance which, using the ingenious methods of modern clearance tests, now enables the investigator to express an opinion on the volume of glomerular filtrate, the permeability of the glomerular membrane, the tone of the afferent and efferent arterioles, the effective renal blood flow, and the maximal secretory and reabsorptive capacity of the tubules.

The bearing of such extensive functional dissections on the problems of normal and pathological renal function is self-evident, and Dr. Hogeman's book, in its details and its broad survey, is an excellent contribution to the subject. The work is based on modern renal clearance tests applied by the author to a large number of normal and pathological cases, the data and methods being given in detail with full statistical analyses. The author's survey of the literature and of his own work brings out effectively the difficulties and differences of opinion, as well as the agreements, in interpreting the results. The effect on these interpretations of the Barclay–Trueta juxtamedullary shunt is considered, and there are interesting discussions about what the urea and creatinine clearances really measure.

Separate chapters are given to the author's findings in normal cases, in glomerulonephritis, in essential hypertension, and in patients with one functioning kidney. In each of these chapters the author's results are integrated with those of other workers, and the book ends with an excellent general discussion and summary.

The author thinks that a simple determination of the filtration rate in acute nephritis is a useful diagnostic aid but that it has little prognostic value. In chronic glomerulonephritis he believes that inulin and diodrast clearances will prove to be a good prognostic guide. In connexion with essential hypertension, he agrees in principle with most other investigators in finding an increase in the filtration fraction, a change which he thinks is best interpreted as the result of increased tone of the efferent glomerular arterioles; but he adds that the Barclay–Trueta shunt may be partly responsible for the change, particularly in older patients and in those whose blood vessels are prematurely aged.

The book contains abundant material of interest to the expert on renal clearance tests. It will be of equal value to the general physician looking for a critical appraisal of the information to be obtained from these tests and of their place in the management of nephritis and hypertension.

J. A. Fisher.

PHARMACY AND PRESCRIBING

A General Survey of the British Pharmacopoeia, 1948. (Pp. 79. 5s. 6d.) London: The Pharmaceutical Press. 1949.

Hints on Prescribing under the National Health Service Act. By J. B. Primmer, M.B., J.P. (Pp. 51. 3s. 6d.) London: Research Books, Ltd. 1949.

Incompatibility in Prescriptions and How to Avoid It. By Thomas Stephenson, D.Sc. Fifth edition, revised by James Burnet, M.D. (Pp. 62. 10s.) Edinburgh: The Prescriber Publishers Ltd. 1949.

What is novel in the new British Pharmacopoeia is the subject of the booklet *A Survey of the British Pharmacopoeia, 1948.* It is a composition annotated from a series of lectures given by several members of the group appointed to prepare the new edition of the *Pharmacopoeia.* The *British Pharmacopoeia* is the standard authority for the control of the purity and constancy of character of medicinal substances. The current edition includes an extensive list of new medicaments as well as revised directions for the standardization of drugs that are not new. Biological therapy and biological methods of standardization of organic products other than pure chemicals form the principal additions. The booklet gives a good description of these changes and affords an illuminative survey of those modern advances in medical treatment that have passed the stage of trial and have attained the status of assured value.

Hints on Prescribing is admittedly designed to effect economy in the administration of the National Health Service. Justification of its purpose need not be questioned, for it is accepted that the patient shall have the most efficient treatment, regardless of cost; but it is obvious

that the earlier the cure the greater the saving, and the guidance here given is the result of approbation derived from experience. This book has a distinct value in that it serves to focus attention on those particular remedies that have upheld their reputation for efficiency in manifold experience over a long period of time, and it may serve usefully to save from oblivion many of the older remedies that tend to become submerged under the increasing numbers of new drugs. The information is conveniently arranged under alphabetically catalogued diseases, and it is in all ways a handy book for prescribers.

Incompatibility in Prescriptions contains the memoranda and the explanations relating to incompatible medicaments. The treatment of the subject of incompatibilities can be generalized only in regard to comparatively few cases, as the one characteristic of incompatibilities is their unexpectedness. Both prescribers and dispensers therefore need a ready-to-hand book of reference for guidance, and this work has been prepared in a useful form for that use The subject-matter is conveniently arranged under an alphabetical system headed by the name of the article to be prescribed, and there is also a good general index.

T. TICKLE

THE HEALING TOUCH

The Healing Touch. By Harley Williams. (Pp. 408; 8 illustrations. 15s.) London: Jonathan Cape. 1949.

Dr. Harley Williams has done it again. In his book *Doctors Differ* he showed that he could make comparatively recent medical history come alive and interesting to lay as well as to medical readers. In *The Healing Touch* he takes such diverse characters as Sir William Knighton, Sir James Clark, and Sir William Jenner—all doctors of royalty; goes on to Chadwick and Southwood Smith and their pioneer work in public health; gives a penetrating analysis of Florence Nightingale; recounts the almost incredible career of Brown-Séquard; and ends with the Mayo family. He has the great gift of dramatizing the people he deals with and makes them live again, and this applies to his many subsidiary characters also. We get sidelights on George IV, Queen Victoria, and many other interesting patients. The final section is not only the story of the Mayo family but that of the rise of modern surgery in the U.S.A., in which Welch, Halsted, and Harvey Cushing are described in a most engaging manner. Billroth and Virchow come in—not dragged in, but as important factors in what was happening in the U.S.A. The book is full of humanity, with wit, humour, and understanding. I congratulate the author on an undoubted success.

ALFRED COX.

The Chemistry of Penicillin, edited by Hans T. Clarke, John R. Johnson, and Sir Robert Robinson (pp. 1,094; illustrated; £9 9s. or $36; London: Geoffrey Cumberlege, 1949), is a very large book of 11 by 8 inches, containing nearly 1,100 pages. It describes a co-operative effort between British and American chemists that was effected during the war by the Medical Research Council in this country and the Office of Scientific Research and Development in the United States. The twenty-nine sections are each on a separate aspect of the chemistry of the drug, and for the most part the authors of each chapter are different. The book therefore describes varied approaches to a single problem, and provides the expert with a fascinating picture of the outlook and resources of his fellows.

Professor Rudolf Thiel's atlas of the diseases of the eye (*Atlas der Augenkrankheiten*; pp 225; M. 60; Stuttgart: Georg Thieme, 1948) is now in its fifth edition. The first edition was a useful students' book, and in the great tradition of German ophthalmology. Subsequent editions appeared during the war. The present volume was published last year, but the additions and expansions are unbalanced and inaccurate, and detract greatly from the value of the original work.

BOOKS RECEIVED

[*Review is not precluded by notice here of books recently received*]

Length of Life. By L. I. Dublin, Ph.D., and others. (Pp. 379. $7.) New York: Ronald Press. 1949.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 29 1949

THE TREND OF NATIONAL INTELLIGENCE

For nearly a century it has been known that in most industrialized communities the birth rate is declining far more rapidly among the wealthier classes of society than among the poorer. What has proved more difficult to determine is whether the difference is a good thing or a bad, or indeed whether it has any social importance whatever. At one time many biologists were inclined to argue that the decrease in fertility was "Nature's way of eliminating stocks that had become effete." Galton and the early eugenists, on the other hand, contended that "if birth control is spreading most rapidly among the more successful members of society, then we must be gradually losing the very type of stock which in the past has been responsible for our national efficiency." Finally, Newsholme,[1] reviewing the data then available, noted that the undeniable facts "have given rise to many Cassandra-like utterances," but concluded that they might be safely disregarded.

A new turn was given to the problem with the development of standardized tests for measuring general intelligence. The school surveys organized in 1913 by the psychologist to the London County Council[2] revealed a distinct negative correlation between size of family and amount of intelligence, quite apart from any difference in social or economic status. A simple calculation showed that if there were no further factors to counteract the obvious consequences then during the following generation the intelligence quotient would fall at the rate of one point or more every 20 years, and (what was much more serious) within the same period "the number of pupils of scholarship ability would be approximately halved, and the number of feeble-minded almost doubled." Somewhat similar correlations were subsequently reported by Bradford at Sheffield, Thomson in the Isle of Wight, and Fraser Roberts at Bath; and Professor Cattell, after an elaborate investigation covering over 4,000 children in Leicester and Devon, declared that the nation seemed "heading for a galloping plunge towards intellectual bankruptcy."[3] In London, however, a repetition of the earlier tests, while suggesting the possibility of a small decline, showed nothing like the change predicted by the more pessimistic computers. In fact, as the original report had pointed out, the general observations of the older teachers, scholarship examiners, and education officials appeared quite inconsistent with the view that any large or rapid changes could be taking place either in the average level of intelligence in the school population or in the numbers of supernormal and subnormal pupils. Burt,[4] indeed, in a summary of the existing evidence prepared at the request of the Royal Commission on Population, suggests that here as elsewhere some compensatory mechanism of a genetic kind might conceivably be operating which would tend to counteract the untoward effects of the differential birth rate.

The whole problem naturally attracted the earnest attention of the Population Investigation Committee, and, in view of the urgent need for more direct evidence, its chairman, Sir Alexander Carr-Saunders, suggested to the Scottish Research Council that a survey which they had carried out for another purpose in 1932 might be repeated and that his committee should be responsible for the cost. The earlier survey, the largest of its kind, had covered a complete age group of Scottish children, numbering in all over 87,000 boys and girls. In 1945 a second survey was organized on similar, but not quite identical lines. A brief report was submitted to the Royal Commission, and a fuller analysis of the data collected has now been published.[5]

The figures obtained, taken at their face value, would suggest that the level of intelligence has actually undergone a slight improvement. This result has plainly come as a surprise to the investigators, and they discuss in detail the most plausible explanations to account for this unexpected change. The most obvious explanation is increased familiarity with psychological tests. If this suggestion be accepted it then still remains conceivable, as the authors observe, that the apparent improvement in test performance may mask a genuine decline in innate ability. On the main issue, therefore, the report is admittedly somewhat inconclusive. Certainly anything like a rapid rate of decline seems out of the question. Nevertheless, if there is in fact a slow but steady diminution, that might well have serious effects in the long run, though its influence might hardly be appreciable after so short an interval as fifteen years. We must await the further survey planned for a later period. Meanwhile the study now published should encourage similar attempts by other bodies and is full of admirable suggestions showing how the requirements of a strictly scientific comparison may be secured in actual practice.

BRONCHIECTASIS

Most chest physicians and many chest surgeons hold strong, but differing, views on the pathogenesis of bronchiectasis. Because it commonly starts in early life the disease was at one time thought to be congenital. This theory has become progressively less popular, but the occurrence of bronchiectasis in association with congenital abnormalities such as complete situs inversus, originally described by Kartagener[1] and subsequently confirmed by others,[2 3] suggests that in some cases the abnormality is congenital, though this can seldom be proved. At the present time most would agree that atelectasis of the lung is an important factor in the pathogenesis. The association was described by Anspach[4] in 1933 and was made familiar in this country by the clinical and experimental studies of Lee Lander and Davidson.[5 6] They pointed out that in a lobe collapsed by the aspiration of mucus the bronchi proximal to the obstructing plugs are dilated by the negative intrathoracic pressure, which in the absence of the cushioning effect of the normally aerated lung acts directly on the bronchial wall. If the walls remain undamaged, and the lung re-expands, the bronchi may regain their normal calibre[6-8]; but if, owing to infection, the normal elasticity of the bronchus has been lost, the bronchiectasis will be permanent.

The experimental work of Tannenberg and Pinner[9] has shown that when complete bronchial obstruction is induced in rabbits distal bronchiectasis occurs only if infection is also present. The infection causes an outpouring of inflammatory products and mucus which actively distend the bronchi. In man this mechanism may be responsible for some cases of bronchiectasis in which the condition develops beyond a complete bronchial obstruction. It is possible that occasionally dilatation of the bronchus is due to a valvular action, but unless previous disease has made the lung parenchyma undistensible such a mechanism should dilate the alveoli rather than the bronchi. In most specimens removed at operation there are signs of inflammation and fibrosis in the bronchial wall, and often also in the surrounding lung.[10-12] Though fibrosis was once thought to be an important cause of bronchiectasis it is now regarded as merely a relic of the original infected atelectasis. Many earlier writers, and some more recent,[13] consider that infection of the bronchial wall is primarily responsible. If that were so, as Mallory[12] has pointed out, bronchiectasis would be mainly a disease of the later age groups in which bronchitis is common. Though he found inflammation of the bronchial wall in 49 out of 50 specimens removed at lobectomy, atelectasis was present in 43 and bronchial stenosis in three others. Carr and his colleagues[17] have recently described a high incidence of bronchiectasis in workers employed filling shells with mustard gas. Here, presumably, there was damage to the bronchial wall; but the authors did not usually see the patients during the acute phase, and atelectasis may well have been a contributory factor. Bronchiectasis is being increasingly recognized as a concomitant of pulmonary tuberculosis, associated either with bronchial narrowing caused by the glandular element of a primary complex[14] or with fibrocaseous disease.[15 16] When accompanying fibrocaseous disease bronchiectasis may give rise to few symptoms, possibly because the bronchiectatic areas are usually in the upper part of the lung and therefore relatively well drained.

According to published reports the prognosis of bronchiectasis is bad. The overall mortality was 27.5% in 789 cases reported in five studies[18-22] published between 1931 and 1941; these patients were followed up for 2–14 years. It must be remembered that most of these were cases severe enough to be admitted to hospital, and in the earlier days bronchograms were less frequently performed on patients with mild symptoms. Fine and Steinhausen[23] reported that of 36 cases discovered through mass radiography 75% had few or no symptoms when seen two years later. Two further studies on the prognosis in children have recently been published. Ford,[24] in Glasgow, has followed up 65 proved cases for 2 to 19 years. Twenty-nine patients with unilateral disease were operated on, with an operative mortality of 17% (five cases). Two died later from other causes; one could not be traced. When seen at follow-up 14 of the remainder had no cough, though they complained of some dyspnoea, and the other seven were improved but still had significant symptoms. Thus of the patients with unilateral bronchiectasis only about 50% were made relatively symptom-free by operation, and there was an appreciable mortality. At least 10 (38%) of the patients not operated on had died; eight of these were under 6 years of age when diagnosed. Ten could not be followed up, but

of the remaining 16 six had no symptoms at all, and in the other 10 there was only minor disability. When studied in retrospect there seemed to be no way of telling which cases would have the good and which the bad prognosis. Wissler and Holtz,[25] in Switzerland, have followed up 38 children with bronchiectasis for 6 to 15 years: nine (24%) were dead, five (13%) had severe symptoms, and the other 24 (63%) were working and had minor symptoms or none at all. Six of the 12 children who originally had severe symptoms had greatly improved during the follow-up period.

Strieder,[26] in a review of the literature on surgery in bronchiectasis, states that the mortality of lobectomy is 1–8%, but that where the disease is bilateral it rises to 15–30%. Only about 50% of cases are suitable for surgery. Of Perry and King's[18] 400 cases, 68% of those operated on were well and working, compared with 37% of those treated medically. These comparisons are, of course, vitiated by the selection of cases for surgery; patients with severe bilateral disease will not be operated on, nor, usually, will those with only minor lesions. Probably operation should be advised in children with unilateral bronchiectasis which has been shown to be irreversible, and in young adults with severe and uncontrolled secondary infection or troublesome recurrent haemoptysis. In other cases medical treatment will be the first choice, and surgery will be a matter for careful individual consideration.

FEES FOR PRESCRIPTIONS

Mr. Attlee's decision that a patient from now on will have to pay a small token fee up to 1s. for prescriptions issued under the National Health Service, while disliked by his supporters in the House of Commons, will be welcomed by the medical profession. One can only regret that this decision was not made earlier. In February of this year[1] we stated in a leading article on the finances of the National Health Service: "The Government may yet consider it wise to ask the patient to make token payments for a doctor's services and for prescriptions. If this were considered feasible it would deter people from making unwarranted calls upon the doctor's time and unnecessary demands for pills and potions." We reiterated this in commenting upon Sir Stafford Cripps's budget hint that a health tax might have to be considered.[2] In his press conference three weeks ago Mr. Bevan categorically stated that "If by tax is meant payment by the patient at the moment when the patient needs treatment, we set our faces against it." Once more we suggested that sooner or later the Minister of Health would have to "introduce some scheme of payment which will be a greater deterrent than mere exhortation to the public to be careful about spending money provided almost entirely out of the taxpayer's pocket." The Government has now had to take a first step in modification of its policy of a health service free of direct charge. This should deter people from making irresponsible demands on the time of general practitioners in order to get ordinary household remedies at the country's expense. There is much to be said for the suggestion made in the *Supplement* of May 7 that the payment for prescriptions should be made by affixing a stamp to the prescription. If some sections of the public continue to make trivial calls on a doctor's time, then the next step of making a token payment to the doctor may have to be considered.

PENICILLIN IN BACTERIAL ENDOCARDITIS

Subacute bacterial endocarditis is one of the diseases in which the prognosis was entirely altered by the introduction of penicillin treatment. During the war encouraging results were reported in the U.S.A., and in 1945, when sufficient supplies of penicillin became available in this country, the Medical Research Council set up fourteen centres to investigate this method of treatment. In 1948 Professor R. V. Christie reported the results of treatment of the first 269 cases in this *Journal*.[1] The conclusion of the investigating committee then was that in 90% of cases the disease could be controlled with a dose of half a million units of penicillin daily, provided that this dosage was maintained for at least a month. The incidence of heart failure after treatment was high. The increase in residual cardiac damage after apparent cure of the infection had already been emphasized by Morgan Jones and his colleagues[2]; these authors also noted that the duration of the disease before the beginning of treatment was the most important factor in prognosis. In the earlier reports there was no conclusive evidence that relapses were due to penicillin resistance of the infecting organisms.

In this issue of the *Journal* Professor Christie summarizes the results of the more recent trials of penicillin treatment in bacterial endocarditis. The original cases have been observed for a further two years, and in addition 189 new cases have been studied. Perhaps the most significant finding in the new report is that the good results obtained with doses of half a million units daily have not been confirmed. Of the patients so treated 20% relapsed or died, as compared with only 7% in the previous report. A second point of interest is that the results of treatment have been directly related to the sensitivity of the infecting organism to penicillin. In the light of this new knowledge it has become necessary to recommend a new system of treatment of bacterial endocarditis, and it is now suggested that the minimal dosage should be two million units daily for a period of four to six weeks. With this dosage cure should be achieved in all cases unless the infecting organism has a coefficient of resistance to penicillin greater than eight. If relapses occur, or if the infection remains uncontrolled, the daily dose should be increased to ten million units. The problem of treating those cases in which the infecting organism is highly resistant remains unsolved. Sometimes an even larger daily dose of penicillin will suffice, and the device of using substances such as caronamide,

which increases the level of penicillin in the blood by suppressing its excretion by the kidneys, is often successful.[3] In some cases other antibiotic drugs should be tried; it remains to be seen how useful aureomycin will prove in these difficult cases.

UPPER LIMB PAIN

The upper limb is subject to a variety of painful conditions from which the lower limb is relatively or completely free. These affections are relatively rare, but even so they are responsible for much pain and disability. In some of the cases there is pressure at the cervico-brachial junction. This condition has recently been the subject of careful study, particularly in this country, and elsewhere in this issue Professor Lambert Rogers reports his findings in thirty patients. It is clear from the evidence that the lowest trunk of the brachial plexus can be pressed against a cervical rib, a rudimentary first thoracic rib, or a tendinous scalenus medius, and that the pain can be abolished by an operation which relieves the pressure. The weakness and muscle wasting, however, may persist for years. The vascular complications are not so easily explained, for Telford and Mottershead[1] have shown that though thrombosis in the main upper-limb artery occurred in 17% of their cases of cervical rib the clot in the majority of these did not extend proximal to the third part of the axillary artery. They found little evidence that the subclavian artery can be compressed and damaged as it leaves the thorax and some support for the view that pressure on the sympathetic fibres in the lowest trunk may play a part in causing the symptoms.[2]

In one important group of cases, usually middle-aged women, acroparaesthesia is characteristic. The symptoms of tingling and numbness in the hand and fingers differ from those of the cervical-rib syndrome in that they are usually bilateral, affect the whole hand and sometimes arm, and are frequently most troublesome at night. Usually no abnormality is found at operation, and scalenotomy and rib resection do not relieve the symptoms, which are in all probability due to traction on the brachial plexus. Professor Rogers is undoubtedly correct in attributing these syndromes to the effects of the upright posture.

A condition which may cause similar symptoms is the "shoulder-hand syndrome," in which there is pain and variable loss of function in the hand and/or shoulder. There is, however, swelling of the hand as a rule, and there may be osteoporosis and other evidence of increased or diminished vascularity. The syndrome may be idiopathic or secondary to peripheral lesions and to lesions of the central nervous system. Steinbocker and his colleagues[3] have studied 42 cases; they consider that the underlying abnormality is a reflex vascular disturbance mediated by an "internuncial pool" of neurones in the grey matter of the spinal cord which spread the stimuli to sympathetic fibres leaving several segments of the cord. This theory is, of course, highly speculative, but it fits in with the finding that sympathetic interruption, by repeated blocks of the stellate ganglion or by sympathectomy, is the most effective treatment.

PSYCHIATRIC TRAUMA AND OBESITY

It has long been known that there was an intimate relation between prevailing mood and the nutritional state of the body. Experiences with neurotic casualties in the last war reminded psychiatrists forcibly of this fact: in many of these patients a loss of two stones or more in weight was combined with neurasthenic, anxious, or depressive symptoms. The relationship could be twofold: on the one hand a severe state of emotional tension might bring about rapid loss of weight despite normal food intake; on the other, a previously stable man might become susceptible to anxieties and fears only after the onset of exhaustion caused by extreme physical exertion and loss of sleep. In the latter case dysfunction of the nervous system could be plausibly attributed to defective cerebral nutrition. The work of Sydenstricker and others had already shown that depletion of vitamin reserves, especially of nicotinic acid, could bring about neurasthenic and even psychotic states. Nevertheless it was rare for physically exhausted neurotic patients to show any clinical sign of avitaminosis. A more complex chain of events seemed probable. Central control of the mechanism of vitamin storage and mobilization was suggested by the finding of Meyer and McLardy[1] that in a proportion of patients dying very soon after a prefrontal leucotomy operation in which an unduly posterior cut had been made there was histological evidence of acute avitaminosis. Clinical findings supported this view, for it had been observed that an acute pellagrous psychosis was specially liable to supervene after subjection to stress, such as childbirth or a major operation, which would be likely to modify central nervous activity, particularly in the hypothalamus.

Elsewhere in this issue Drs. H. J. Shorvon and J. S. Richardson discuss a related problem, but posed in an opposite form. They describe three cases in which sudden, large, and rapid increases of weight occurred soon after psychologically traumatic experiences, such as the death of relatives and bomb incidents. In one case the increase in weight dated from a confinement. All three patients were women, and in two the weight increase was associated with menstrual disturbances, but there was no evidence of endocrine disturbance. Much of the weight increase could be attributed to water retention, which is controlled by the pituitary and the hypothalamus, but there was also accumulation of fat without a specific type of bodily distribution. While the early and rapid increase in weight could be put down to water retention, a gradual deposition of fat is more probably responsible for the persistence of obesity over several years.

The authors scrupulously refrain from speculation, but the possibility must be considered that events which cause fear and grief may, in special and rather unusual circumstances, cause a persistent disturbance of hypothalamic function. It is not clear whether the disturbance should be regarded as inhibitory or excitatory or both. Physiologically some of the findings resemble the results of stimulation of hypothalamic nuclei; others those of a destructive lesion in this region. There is no essential

difference between such a change in hypothalamic activity and the corresponding cortical change that shows itself in a persistent tremor or paralysis after psychological shock. But in the cases reported by Shorvon and Richardson the physical abnormality may be ascribed to a "hysterical" disturbance of vegetative function instead of a disturbance of muscular control.

The reversible nature of the phenomenon is made clear by the results of treatment. All the three patients responded to abreactive psychotherapeutic measures. Two explanations of the value of abreaction have so far been suggested, psycho-analytical and physiological. Sargant and Shorvon[2] proposed the theory, derived from Pavlov's work on conditioned reflexes, that a hysterical conversion symptom could be regarded as the effect of inhibition or of spontaneous and stereotyped activity in a partially isolated functional system in the cortex. This suggestion bears a close resemblance to the concept of the "reverberating circuit" put forward by Wiener[3] as a possibly useful analogy from the field of electronics. The isolation of the cortical system might then be overcome, and more complete central integration be re-established, by bringing about a general cortical excitation and discharge. Sargant[4] has suggested that other methods of physical treatment, such as electrical convulsive therapy, possibly depend for their success on the breaking-down of functional barriers by cortical excitation. Speculations of this kind are open to many objections, but development of the ideas they contain by experimental and clinical research may lead another step on the road towards a solution of the body–mind problem.

B.C.G. VACCINATION

A lively correspondence in the journal of the Danish Medical Association has shown how difficult it is to be absolutely unanimous about anything. The two points under discussion were: Who is to vaccinate with B.C.G., the general practitioner or the tuberculosis specialist? and, How early in life are Danes to be vaccinated with B.C.G.? The first question was raised by Dr. J. Riising,[1] who argued that the general practitioner is quite capable of practising B.C.G. vaccination and that there is something to be said against sending a child a long way to a tuberculosis dispensary where the vaccination may be carried out by a nurse. Dr. U. Gad[2] answered by pointing out that B.C.G. vaccination by general practitioners is liable to interfere with the diagnostic and prophylactic procedures at tuberculosis dispensaries, at which a radiological examination can be made as a preliminary to vaccination. Experienced B.C.G. vaccinators, he argued, see relatively few complications. Furthermore, the interpretation of tuberculin reactions is full of difficulties. In a later letter Dr. Gad[3] remarks that the difference between himself and Dr. Riising may ultimately be settled by putting B.C.G. vaccination in the hands of an ambulant team, similar to those which the Red Cross has organized. As for the second question, the opinion seems to be growing that in principle B.C.G. vaccination should be undertaken as early as possible, even in infancy. Dr. Gad, however, considers that the B.C.G. vaccination of the newborn, as carried out in Sweden on a large scale, may not be necessary in Denmark except in a tuberculous environment, "as the newborn are poor antitoxin producers, and as we have less tuberculosis than in Sweden." Dr. P. Hertz[4] refutes the argument that the newborn are poor antitoxin producers, and he points out that more than 90% of the newborn who have been vaccinated with B.C.G. in Sweden have been rendered tuberculin-positive. In his own experience of 64 newborn infants recently vaccinated in Copenhagen he has found it necessary only in two cases to repeat the operation in order to achieve a positive tuberculin reaction. In a more detailed study Dr. Hertz[5] has reported on his successful vaccination with B.C.G. of 537 infants from 0–12 months old. None of the six deaths among these 537 infants was due to tuberculosis: hence his conclusion that "one ought not to delay too long in proposing the voluntary Calmette vaccination of all infants, and preferably the newborn." Professor H. C. A. Lassen[6] writes in the same sense, and he argues that the forty to fifty deaths from tuberculosis which still occur every year in Denmark among children under the age of 5 years are a standing reproach to those authorities who delay in applying B.C.G. vaccination to children of this age.

FRACTURE OF THE BRONCHUS

Traumatic rupture of the bronchus is a rare injury. In suspected cases the diagnosis should be confirmed by bronchoscopy. Immediate thoracotomy and repair may save life in some cases and prevent serious complications in others. Care must be taken to preserve the bronchial blood vessels. Kinsella and Johnsrud[1] in 1947 published a review of 38 cases, adding two of their own. A crush injury which shears either main bronchus at or near the carina was the usual cause of rupture. In more than half the cases it was fatal. Commonly associated with fracture of the bronchus were haemorrhage—causing haemoptysis, atelectasis, or haemothorax—and leaking of air, causing pneumothorax or mediastinal emphysema. In patients recovering from the injury a bronchial stricture develops, leading to obstructive collapse and mediastinal shift. Artificial pneumothorax to ameliorate the resulting dyspnoea has had good results. In one case secondary infection was successfully treated by pneumonectomy. Endoscopic dilatation was not found of much value. In 1945 Sanger[2] described two cases in which he had sutured tears of the bronchus due to penetrating shell fragments, but the first case to be treated by resection and anastomosis has recently been reported by Griffith.[3] The patient was a woman who was thrown against the steering-wheel in a motor-car accident, injuring her face and crushing her chest, with fracture of ribs on the left side. Dyspnoea was severe for a few days, but recovery was rapid. Later she became dyspnoeic again; her chest was "wheezy," and she had a dry cough. Radiographs two months after the injury showed obstructive emphysema of the left lung in expiration, and on

[1] *J. thorac. Surg.*, 1947, 16, 571.
[2] *Ann. Surg.*, 1945, 122, 147.
[3] *Thorax*, 1949, 4, 105

auscultation a loud rhonchus was heard. At bronchoscopy an elastic stricture of the left main bronchus was seen. It was due to mal-union of a simple fracture, with overriding of the cartilage, and it could not be cured by dilatation. Operation was therefore advised, and was carried out six months after the accident. Through a left thoracotomy the stricture was excised, except for a bridge of posterior wall carrying the bronchial artery, and end-to-end anastomosis was done with interrupted stainless steel sutures. The patient's recovery was uneventful; her symptoms were relieved, and the bronchus healed normally.

BONE LENGTHENING

Inequality of more than two inches (5 cm.) in the length of the lower limbs is a serious handicap. Attempts to equalize the limbs by both lengthening the shorter or shortening the longer have been successful. Codivilla[1] in 1905 first attempted to lengthen a limb by repeated forced pull on a nail transfixing the os calcis after oblique oesteotomy of the femur. Similar operations were carried out in 1912 by Freiberg,[2] and in 1913 by Magnuson[3] and by Ombredanne.[4] In 1921 Putti[5] published a paper on operative lengthening of the femur; he used skeletal traction and countertraction directly on the femur. In 1927 a method of tibial elongation was described by Abbott[6] in which the steps were lengthening the tendo achillis, osteotomy of the fibula, insertion of the drill pins, osteotomy of the tibia, division of the tibial periosteum, division of the interosseus membrane and fibular intermuscular septum, and finally application of the distraction apparatus. The complications of this procedure were forward bowing of the tibial fragments, overstretching, interference with the blood supply of the fragments, and insufficient fixation of the fragments.

Leg lengthening is indicated when the difference between the limbs exceeds one and a half inches (3.8 cm.); less than this can be easily compensated by pelvic tilting and shoe raising. Only young patients are suitable, and the operation should not be undertaken after a recent acute infection or in cases with severe paralysis of the affected limb. A very large difference between the length of the limbs is also a contraindication. Success depends on the use of an apparatus which will confine movement of the fragments to the long axis of the bone, and Allan[7] has been successful in producing an instrument which secures this. He performs an oblique osteotomy of the tibia about four inches (10 cm.) in length, leaving the periosteum intact as far as possible, and a transverse osteotomy of the fibula. Two Kirschner wires are inserted in each fragment and fixed to the distraction apparatus, and a carefully padded plaster is applied from toes to groin. When set, the plaster is divided, so that in effect each section of the limb is in a separate plaster cast. With this method Allan has found it possible to lengthen the bones at the rate of 1/16 in. (0.15 cm.) daily. Femoral lengthening has proved to be less practicable, owing to the difficulty of placing the transfixing wires and the complication of knee stiffness. Allan used leg lengthening in cases of tuberculosis of the hip and knee, in congenital shortening, in pyogenic bone and joint infections which had been quiescent for more than six years, and in patients with infantile paralysis treated by sympathectomy as a prior condition. Most patients were 13 or 14 years of age, but it was found that in adults the bones united just as readily.

Muscles react badly to stretching, and much wasting occurs. Periosteum, membranes, and fascia are not easily stretched, and their lengthening probably causes most of the pain experienced. Blood vessels withstand the procedure well: nerves, however, are more liable to damage, especially the lateral popliteal nerve. Knee stiffness and displacement of the ends of the fibula are additional complications. Skin sloughing over the operation scar was noted when a gain of more than three inches (7.5 cm.) in tibial length was obtained. Allan states, however, that two inches of lengthening may be gained in the femur, and three in the tibia, without any complication. It cannot be denied that bone lengthening is a painful and formidable procedure. White goes so far as to state that in his experience the result seldom justifies the effort employed, since great force is needed to stretch the tissues in an already damaged limb. In many cases shortening of the longer leg has proved to be much the better method, being simpler and less hazardous.

THE MANUFACTURE OF CORTISONE

In a recent annotation[1] we referred to the discovery that "cortisone" ("compound E") could be prepared from sarmentogenin, a substance which can be isolated from the seeds of the African vine *Strophanthus sarmentosus*. It is now known that the common yam of tropical America, *Dioscorea mexicana*, yields a substance, botogenin, which can be used as a starting-point for the preparation of cortisone,[2] and many more plants may be found to be possible sources of cortical hormones. In the meantime pharmaceutical manufacturers in the U.S.A. are co-operating in order to increase production of cortisone from ox bile. According to a recent report[3] one company is to quadruple its plant for the manufacture of desoxycholic acid from the bile of cattle slaughtered in the stock yards. A spokesman of the company said that desoxycholic acid can be prepared from the cholic acid in bile in much larger amounts than would be obtained by isolation of the natural substance from the same quantity of bile. Nevertheless, the quantity of desoxycholic acid which will be prepared in a year from the bile of 200,000 cattle will yield only about 2,700 g. of cortisone. This represents 27,000 doses of 100 mg.—a very small amount even for limited research purposes.

Mr. V. Zachary Cope, M.S., F.R.C.S., will deliver the Bradshaw Lecture before the Royal College of Surgeons of England (Lincoln's Inn Fields, London, W.C.) on Thursday, November 10, at 5 p.m. His subject is "Visceral Actinomycosis and its Treatment."

REFRESHER COURSE FOR GENERAL PRACTITIONERS

FAILED FORCEPS

BY

F. J. BROWNE, F.R.C.S., F.R.C.O.G.

Emeritus Professor of Obstetrics and Gynaecology, University of London

The term "failed forceps" is applied to the type of obstetric case in which an attempt has been made to deliver with forceps but without success. The causes of failure have been fully discussed in papers in this *Journal* and elsewhere by Phillips, Farquhar Murray, Miller, Fletcher Shaw, Stacey, and Claye, and are chiefly as follows.

Contracted Pelvis and Disproportion

In one-third of Miller's 558 cases of failed forceps this was the cause, either alone or combined with a posterior position of the occiput. The difficulty arises mostly from failure to recognize insuperable disproportion between the foetal head and the pelvis, or because in cases of moderate disproportion the forceps is applied too soon and before sufficient time has been given for the head to mould and to descend far enough into the pelvic cavity. Incredible as it may seem, in over 50% of Miller's cases the head was still free above the brim on admission to hospital after attempts at forceps delivery outside had failed. One of the elementary rules regarding the application of forceps had thus been broken.

The most frequent cause of disproportion is contracted pelvis. Severe degrees of contracted pelvis due to rickets are now rare, but minor degrees of contraction, especially of simple flat and generally contracted pelvis, are common and apt to be overlooked before labour sets in if certain simple rules are neglected.

(1) In a primigravida the foetal head should engage deeply in the pelvis in the last two weeks of pregnancy. If it does not do so a reason must be sought. A common cause is contracted pelvis, and this condition should always be excluded. This may be done by simple clinical methods —measuring the patient's height (under 5 feet (1.5 m.) is always suspect), looking for rickets, and measuring the diagonal conjugate—but the present tendency is to use *x*-ray pelvimetry, which alone can give accurate measurements of the diameters, including the true conjugate, and the interspinous diameter of the outlet. Disproportion, which is rare in the absence of pelvic contraction, can be assessed by Munro Kerr's modification of Muller's method, with or without anaesthesia.

(2) In multigravidae the history of past labours may give warning of possible trouble. For example, in one of the cases of failed forceps recorded by Fletcher Shaw the woman had had four previous confinements, two of which ended in craniotomy and two in caesarean section.

Unrecognized Unrotated Posterior Positions of the Occiput

This occurs mostly in primiparae. In all the series referred to above it was the second most frequent cause of failure. It is necessary to stress once more the importance of a thorough examination of all patients before applying the forceps, first by abdominal palpation and then per vaginam, if necessary with the whole hand in the vagina under deep anaesthesia. It is necessary to make sure of the following points: (1) that the os is fully dilated; (2) that the occiput is anterior; (3) that the head has descended at least to the level of the ischial spines. These can be easily felt on each side and mark the level of the pelvic floor. Application of forceps to a head above the spines is a "mid forceps" application, below this a "low forceps."

Abdominal examination will reveal much. It will show how far the head has descended into the pelvis. If any part of the head is felt on abdominal palpation delivery is likely to be difficult and may even be dangerous for the child. Occipito-posterior positions cannot usually be diagnosed abdominally but only by introduction of the whole hand into the vagina under deep anaesthesia.

There are two ways of diagnosing persistent occipito-posterior cases. The first and most commonly used is to feel the ear—its free border is directed towards the occiput. It should be remembered that the ear may be folded forward, and this may give rise to doubt. Another plan is to feel for the nape of the neck. When this is found—a smooth flat surface—the forefinger can be passed a little farther on to the anterior shoulder and the head and body rotated by the internal hand alone in one single movement, if possible without dislodging the head out of the pelvic cavity. There is only one fallacy that I have found in this method of diagnosis: if the head is much moulded the forehead may be so elongated that it is mistaken for the neck. This error can be avoided by keeping the possibility in mind and pushing the exploring hand a little farther on. If it is the forehead the finger will come to the face instead of the flat back and shoulder. It should be noted that slipping of the forceps is almost always due to its application to an unrotated occipito-posterior. If this happens the blades should be removed and the position reassessed.

Application through an Undilated Cervix

In 50% of Claye's cases this was the cause of failure. As every student is taught that full dilatation is necessary before application of forceps the mistake can only arise through difficulty in diagnosing full dilatation. Claye has a useful word on this. "If," he says, "the cervix is fully dilated the head has come so far through it that its rim is no longer palpable. If the cervix is palpable it is not fully dilated." To this the writer would add that "full dilatation" means full dilatation between pains. Too often the medical attendant examining the patient (as is correct) during a contraction and finding the head descend and no rim of cervix palpable concludes that the os is fully dilated and decides to apply forceps. When the patient is anaesthetized, however, he may find that the os is only three-quarters or less dilated. By that time all preparations have been made for forceps, and if inexperienced the doctor may not have the moral courage to desist and confess his error. It is always wise, therefore, in assessing dilatation of the cervix before application of the forceps, to keep the examining finger in the vagina after the pain has passed off.

Application of forceps through an imperfectly dilated cervix most commonly takes place in primiparae in whom the first stage of labour has been prolonged, and especially

if the membranes have ruptured prematurely. These are always anxious cases. There may be disproportion or an occipito-posterior position, in both of which cases labour tends to be slow and pains poor. But often neither of these is present and the delay is then generally due to primary uterine inertia. If the membranes are unruptured the long first stage does not matter much, though it tries the patience of all concerned. If the membranes have ruptured prematurely, however, the life of the foetus is then endangered, because as liquor trickles away the uterus is allowed to retract excessively and progressively diminish the area of attachment of the placenta and the foetal and maternal circulation through it. If it proceeds far enough this will cause foetal asphyxia and intrauterine death. These cases can be very anxious ones, and little can be done except to give a sedative, keep the bowels and bladder empty (a warm soap-and-water enema often stimulates strong contractions), and avoid fussy and repeated vaginal examinations. The foetal heart sounds should, of course, be examined at intervals. Most of these labours end spontaneously or the patients are easily and safely delivered by low forceps; but in a few cases anxiety arises because the foetal heart sounds indicate foetal distress before the cervix is fully dilated. The best course to adopt then needs both experience and good judgment. It is often possible to complete the dilatation of the cervix manually and apply forceps, but this is always a hazardous procedure for the child, especially as the dilatation is apt to be imperfect. If the cervix is thinned out over the head it may be divided at 5 and 7 o'clock by scissors after applying the forceps and drawing the head gently downwards. But more and more of these cases are now being treated by lower-segment caesarean section, which is usually much safer for both child and mother.

Constriction Ring

This is one of the more infrequent causes of failure. It may be the only cause or it may complicate contracted pelvis or unrotated occipito-posterior cases. Usually the head descends fairly well when forceps traction is made, but it quickly recedes again when traction is stopped. This should make one suspicious, but the condition can only be diagnosed by removing the blades, inserting the finger, and feeling the ring as hard as iron around the neck. In such cases the forceps should be reapplied and one capsule (3 minims: 0.18 ml.) of amyl nitrite crushed on gauze under the patient's nose so that she may inhale it. Relaxation takes place immediately, but is temporary. The forceps should therefore be in place for delivery without unnecessary delay. An alternative method is to inject subcutaneously 7 minims (0.62 ml.) of 1 in 1,000 adrenaline.

Finally, a certain number of failed forceps cases arise through application of the instrument to a hydrocephalic head, an undiagnosed breech, a mento-posterior or brow presentation, or when there is obstruction by a pelvic tumour.

Should the Forceps be Applied or Not?

On each blade of the forceps there should be a large question mark. On taking up the first blade and seeing the question mark the operator should ask himself, "Are the conditions present that make the application of forceps safe—the membranes ruptured, a vertex presentation with the occiput anterior and the sagittal suture in the antero-posterior diameter, the bladder and bowels empty, the lower pole of the head at least at the level of the ischial spines, the os fully dilated?" On taking up the second blade he should ask himself, "What are the indications justifying the application of forceps in this case?" Apart from the case when the head is on the perineum, when application of forceps (preferably preceded by episiotomy in a primipara) is always safe, there are only two real indications for forceps—maternal or foetal distress.

Finally, we should all of us keep in mind the words of our master, Smellie. "Students should never think themselves perfect; for after all the instruction that can possibly be conveyed there are many things in midwifery that can only be learned by practice and observation; and cases will sometimes arise which will puzzle and foil the best practitioners."

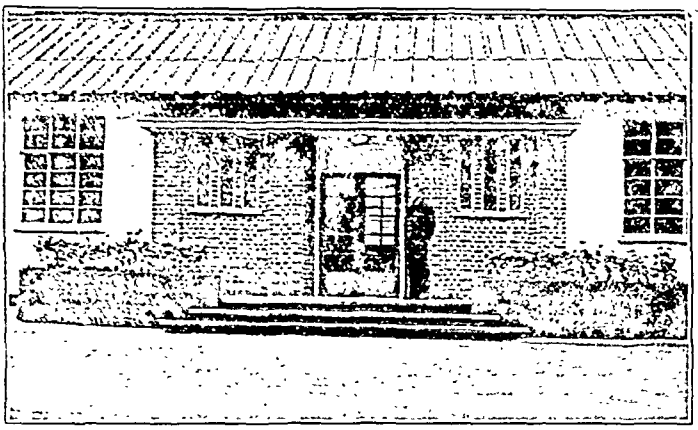
Preparations and Appliances

HOSPITAL SYRINGE SERVICE



Mr. P. G. MERRETT, theatre technician, St. Thomas's Hospital, writes: In modern anaesthesia the use of 2-ml. syringes both for immediate and for intermittent use during operations seems to have increased with the introduction of curare and its antidotes. I thought, therefore, that a method of packing syringes ready for supply at a moment's notice would be acceptable, and have devised the following contrivance, which has met with the approval of most of the anaesthetists at this hospital. The type of sterilization is by dry heat.

As the accompanying diagram shows, the requirements are heat-resistant syringes, oven-glass tubes, "cellophane," and a small rubber band to seal and secure the end of the tube when ready for sterilizing. Care of the needle-point is important, and for this purpose use is made of a piece of the brass needle-holding tray supplied by most manufacturers with new needles. The unwanted clips are flattened, leaving one for each guard, and cut out as shown. This guard is easily clipped to the needle-butt and hand-shaped so as to be deflected from the point of the needle. The tapered end is curved inwards slightly to fit the bottom of the glass tube, and serves as a protection to the whole. This method has stood up to normal use. If required, an absorbent cotton roll, as used for dental purposes, can be inserted alongside the needle. This provides a swab for cleaning the area of injection, and can be used to protect the needle if the syringe is required for intermittent injection. Most anaesthetic trolleys could carry a small bottle of surgical spirit.

There is no doubt the method could be adapted for other branches of medical, surgical, and laboratory work, and it might be handy in a central supply depot.

A set of pictures for public display has been prepared on "Coughs and Sneezes" by the Central Office of Information. Local authorities may obtain these sets from the C.O.I. (Room 2301), Block 2, Montagu Mansions, Crawford Street, Baker Street, London, W.1.

THE BROMPTON HOSPITAL

INSTITUTE OF DISEASES OF THE CHEST

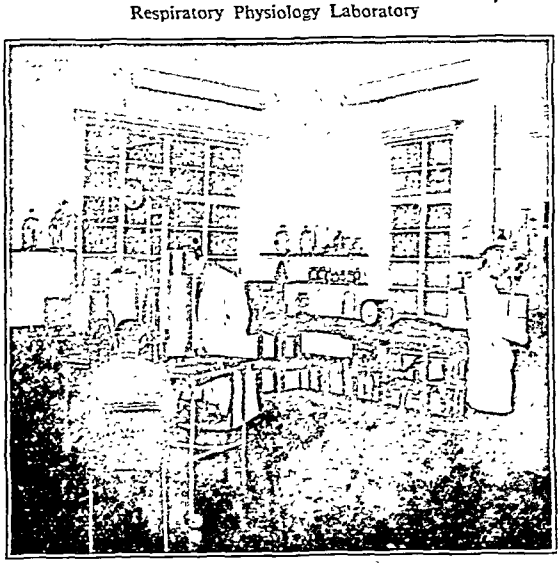
The opening this week of the new building of the Institute of Diseases of the Chest at the Brompton Hospital carries one stage further a recommendation in the *Report of the Inter-departmental Committee on Medical Schools*, 1944 (the Goodenough Report). At that time the British Postgraduate Medical School provided opportunities for study in medicine, surgery, obstetrics, gynaecology, and pathology, but made no use of the unrivalled facilities available in the special hospitals in London for the study of particular branches of medicine and surgery. The report recommended the reorganization of the British Postgraduate Medical School as a Federation, with clinical institutes not only in general medicine and surgery at Hammersmith but also in association with the principal special hospitals. Accordingly the British Postgraduate Medical Federation was established, and institutes at the special hospitals are now in various stages of development.

At the Brompton Hospital postgraduate instruction has been given for many years, and until 1939 some undergraduate teaching also. The Medical School of the Brompton Hospital was included in the list of institutes having recognized teachers of the University of London, the teaching taking the form of short intensive courses, including informal attendance in wards and out-patient departments of the hospital.

Following publication of the Goodenough Report, efforts were made to improve the academic status of the School in order to conform to the suggested scheme for postgraduate education. Early in 1946 a programme of postgraduate teaching was begun which has been continued since then with very little modification. During university terms courses of study consist of clinical work in the wards and out-patient departments; radiological, pathological, and clinical demonstrations and discussions; and lectures. A less formal type of instruction is continued during the summer vacation. The Medical School of the Brompton Hospital was always financially independent of the Hospital. In May, 1947, its name was changed to "The Institute of Diseases of the Chest." Since 1946 the British Postgraduate Medical Federation has given it financial support. The teaching activities at the Postgraduate Association of the London Chest Hospital, begun in 1924, now come under the umbrella of the Institute.

The new building now formally opened consists of a single-story building adjoining the west side of the main block at the Brompton Hospital. Accommodation includes laboratories, a library, a museum, a lecture theatre, a photographic department, a common room for students, a refectory, and administrative offices. Begun in May, 1948, the building was completed in the summer of 1949.

The Institute provides postgraduate instruction and facilities for research in diseases of the chest. As to the former function, the most important aspect is the training of physicians and surgeons wishing to specialize in diseases of the chest. After courses of study lasting for one or more terms it is intended that a proportion of the students shall obtain graded hospital appointments, the number of which has increased during the past few years to meet the needs of the Institute. The research facilities of the Institute will, it is hoped, play an important part in training the specialists of the future. When circumstances permit, advanced revision courses for established specialists will be conducted. The Institute will also provide, when possible, instruction as part of the training of general physicians. No undergraduate teaching is now given.



About thirty-five to forty postgraduate students attend each term, of whom 12 are working whole-time. They spend one day a week at the London Chest Hospital and the rest of their time on clinical work in the wards and at clinical demonstrations. Preference is given to those who are specializing in diseases of the chest; the remainder are part-time students studying for the M.R.C.P. and other examinations. The Institute will try to meet the enormous demand for training in thoracic surgery. At present only temporary arrangements have been made, but it is hoped eventually to appoint a surgical subdean who will co-ordinate and expand tuition in thoracic surgery.

Almost half the accommodation of the Institute is devoted to research laboratories, including a laboratory of respiratory physiology. Pathology is not included; though the museum and its preparation room are housed in the Institute the pathological laboratories remain in the hospital.

The Dean is Dr. J. G. Scadding, and Drs. Kenneth Donald, J. W. Crofton, and J. R. Bignall hold appointments on the staff of the Institute. The staff of the Brompton and London Chest Hospitals take part in the teaching at the Institute.

Now that the new building is completed and equipped, it awaits only approval and inspection by the University of London before it acquires the full academic status of an institute of the British Postgraduate Medical Federation and takes its place as the principal training centre in this country for the chest specialists of the future.

Respiratory Physiology Laboratory

THE CARE OF OLD PEOPLE

ADDRESS BY SIR WILLIAM DOUGLAS

Representatives of nearly three hundred voluntary organizations and of nearly as many local authorities assembled at Friends House, London, for the fourth annual conference of the National Old People's Welfare Committee, which works in association with the National Council of Social Service. One subject for discussion, under the chairmanship of Sir Ernest Rock Carling, was the employment of old people, and an open forum was held on matters affecting old people's welfare.

At the opening session Sir William Douglas, Secretary of the Ministry of Health, addressed the conference on what has been planned and achieved by local authorities and voluntary bodies since the passing of the National Assistance Act, 1947. After mentioning that in that year the total number of people of pensionable age was 13.7% of the population, Sir William Douglas discussed methods of encouraging old people to continue to live an independent life for as long as they could, and the importance of ensuring that old people who could not look after themselves would be cared for with kindness and understanding.

The withdrawal of old people from normal community living, he said, should be postponed for as long as possible, and geriatric treatment had helped towards this desirable end. For the most part the 95% of old people living by themselves or with their families did not want to be thought of as segregated from the community, but if they were to continue to lead an independent life some consideration must be given to their special needs—especially in the matter of housing. Too many old people were living at the top of high buildings; others in large houses where they had formerly brought up families. Some local authorities had provided bungalows and flats specially designed for the aged, but much remained to be done in that respect. The Ministry of Health was encouraging local authorities to include in their programmes houses of varying size. The Housing Act, 1949, enabled Exchequer assistance to be given to housing authorities for the provision of hostels for those who no longer required or desired a separate home of their own. He feared that a long time must elapse before an adequate number of old people's dwellings could be built.

To ensure that old people got adequate meals various provisions were made, notably the "Meals on Wheels" service. The Women's Voluntary Service were serving 50% more meals from their centres than was the case a year ago. Civic restaurants would arrange for meals to be taken round their districts. The Ministry of Health would grant sanctions for loans to enable local authorities to buy vehicles and equipment for this service. The movement to establish old people's clubs had been greatly facilitated by grants under Section 31 of the National Assistance Act. Up to last July there were 1,800 such clubs.

There had also been a large extension of the home help service, offering unlimited scope for voluntary effort in helping old people. Many of them, too frail to leave their homes, appreciated help with shopping and certain household work, or just a friendly visit, with any desired advice on their personal difficulties. For old people who could no longer live a wholly independent life some residential homes had been established, at which the weekly minimum charge was 21s. Subsidies were available for the building or acquisition of houses suitable for this purpose.

As for the bedridden, Sir William Douglas said that he looked forward to the day when no old person would be condemned to bed in the casual manner which had obtained in the past. Each such case should be carefully examined and considered from the point of view of the possible restoration of function. Some, of course, must always remain in the care of the hospital service, requiring constant care and supervision. It was very important to give them a sense of security; they should not be removed from one establishment to another except on strong medical grounds. It was difficult to escape the conclusion that some special accommodation for the aged infirm would have to be provided.

Reports of Societies

FATS IN NUTRITION

A conference of the Nutrition Society on "Triglyceride Fats in Human Nutrition" was held in the medical school of Birmingham University on October 15, with Sir Leonard Parsons, F.R.S., presiding.

Professor T. P. Hilditch spoke on the chemical constitution of natural fats, which were all complicated assortments of mixed triglycerides. In the formation of individual glyceride molecules a principle of even distribution of fatty acids between the glycerol molecules usually held good; no fat molecule contained two radicles of any particular acid unless all the other molecules contained at least one radicle of that acid. The compositions of certain animal fats, however, did not appear to obey this rule: Thus beef and mutton fats contained glycerides with more than one radicle of stearic acid in greater amounts than might be anticipated. Human depot fat contained 24% of palmitic acid, 8% of stearic acid, and 3% of myristic acid as its saturated components, with 47% of oleic acid, 5% of palmitoleic, 10% of acids of the linoleic type, and 3% of C_{20-22} acids as its unsaturated components. Liver glycerides differed in composition both from the storage fats of the same animal and from the corresponding liver phosphatides. In some animals the milk fat closely resembled the depot fat, but in others it differed in containing large amounts of short-chain acids. Human milk fat was unique in containing lauric acid and a little capric acid, but no acids of lower molecular weight.

The ability of animals to synthesize fats from carbohydrates had long been recognized. Recently the synthesis of palmitic, stearic, palmitoleic, and oleic acids had been proved, but it remained doubtful whether other acids could also be produced. Dietary fat might be absorbed by the animal, provided that it melted, or at least softened, at body temperature, but it was uncertain whether an animal could utilize fatty acids which did not usually occur in its body even if they were ingested as glycerides of low enough melting point. The inclusion of vegetable fats in the diet might alter the composition of the animal's depot fat, but acids of low molecular weight were not stored. Vegetable fats varied greatly in composition, some being almost saturated and others highly unsaturated. Marine oils were usually characterized by the presence of large amounts of unsaturated C_{20-22} acids. In artificially hardened fats, as used for the manufacture of margarine, only small amounts of doubly unsaturated acids were present, since the hydrogenation process first reduced all the acids to single unsaturated linkages before completely saturating the acids first attacked.

Dr. P. Kraut said that the production of artificial fats from acids formed by the catalytic oxidation of petroleum had been studied in Germany at various times since the first world war. The crude acids so produced differed from those of natural fats in containing equal numbers of odd and even carbon chains, in the absence of unsaturated components, and in the presence of dibasic acids, branched chain acids, alcohols, aldehydes, and various other contaminants. Dibasic acids did not appear to be injurious, but the removal of the other impurities was a tedious procedure. Although by repeated purifications it had been possible to produce tasteless fat which appeared to be innocuous when given in small quantities to experimental animals and man, the high cost involved was only justifiable in time of war. In any case the general use of artificial fats in human nutrition could not be recommended without further extensive feeding trials.

Study of Fat Absorption

Dr. J. M. French outlined methods for the quantitative and qualitative investigation of fat absorption. To find the amount of fat absorbed from the intestines the faecal excretion of fat must be balanced against the dietary intake over a period of at least three to five days. For estimating the efficiency of absorption a standard diet containing 50 g. of fat daily was usually given, but sometimes 100 g. or more was included

Useful information could often be obtained by changing the quality of the dietary fat, particularly by increasing its content either of saturated short-chain acids or of unsaturated fatty acids. To elucidate the nature of defects in fat absorption it was often instructive to compare the qualities of the dietary and faecal fats, and for this purpose estimations of molecular weight and iodine value were useful.

In order to understand changes in the mechanism of fat absorption the intraluminar, cellular, and distributive phases must be considered. During the intraluminar phase fat was prepared for absorption partly by hydrolysis and partly by fine emulsification. In the cellular phase it passed through the intestinal cell, probably undergoing further modifications involving phospholipoid formation. In the distributive phase it left the intestinal cell and was either carried by way of the lymphatic vessels, the thoracic duct, and the systemic blood stream into the fat depots, or alternatively by way of the portal blood stream into the liver. The choice between these two routes depended on the degree of hydrolysis. Short-chain acids, which were readily detached from their glycerides, were mainly absorbed in a non-particulate, molecularly dispersed form in aqueous solution by the portal route; long-chain triglycerides, which formed a large part of the normal diet, were absorbed in particulate, emulsified form by the lymphatic route.

To find whether ingested fat underwent normal intraluminar changes specimens of the intestinal contents of patients could be withdrawn by means of a Miller-Abbot tube; the degree of dispersion and stability of the fat particles could then be examined, and estimations made of amylase, lipase, trypsin, lysozyme, and phosphatase. Tests of the efficiency of particulate absorption could be made by giving a long-chain triglyceride as a test meal, and by examining the resulting systemic lipaemia three hours later by means of the chylomicrograph or by microchemical estimations of fatty acids. When it was suspected that defective particulate absorption was accompanied by an increased absorption of fatty acids by the portal route, decreased gastric acidity and motility should be looked for, and also the possibility of excessive mucus formation in the small intestine should be investigated. In checking the normal functioning of the intestinal cells their power to absorb substances other than fat might be tested; the rate of disappearance of glucose when introduced in small amounts into the intestine often provided useful information. Excessive carbohydrate fermentation could be detected by estimating the increased amounts of volatile acids present in the intestines.

Dr. H. G. SAMMONS then described an ingenious apparatus by which it was possible to estimate the amount of fat present in a few drops of blood.

Types of Defective Fat Absorption

Professor A. C. FRAZER, whose article on "Fat Metabolism and the Sprue Syndrome" appeared in the *Journal* of October 8 (p. 769), discussed normal and abnormal fat absorption in the human subject and its nutritional significance. He said that normal subjects absorbed 95% or more of their dietary fat, but two types of defective absorption could be recognized. First, a deficiency of bile or pancreatic secretion might cause only 10–20% of the ingested fat to be absorbed. The faecal fatty acids were then found to resemble those of the dietary fat in composition, there was no evidence of abnormal gastric secretion or motility, and if the fat content of the diet was raised there was no corresponding increase in the absolute amount of fat absorbed. Secondly, patients who appeared to have a normal biliary and pancreatic secretion were often found to be able to absorb only 50–70% of their dietary fat. The faecal acids were particularly rich in long-chain components, gastric secretion and motility were abnormally low, and an increase in the dietary fat was usually accompanied by a rise in the absolute amount absorbed. In this second type of defect, in which reduced particulate absorption was presumably associated with normal non-particulate absorption, the failure of acid formation in the stomach made the *p*H of the small intestines much less subject to sudden changes. In these circumstances bacteria were able to thrive at abnormally high intestinal levels, which allowed them to hydrolyse fats, ferment carbohydrates, and utilize nutrients such as nicotinic acid, riboflavin, and folic acid in competition with the normal metabolic processes of their host. The whole pattern of intraluminar activity might thus be changed, and minor digestive delays or embarrassments might become of major importance in precipitating secondary nutritional deficiencies.

Intravenous Alimentation

Dr. J. J. ELKES described attempts to prepare fat emulsions suitable for use in intravenous alimentation. Besides being physically and chemically stable such emulsions should be compatible with protein and glucose for simultaneous administration, and should not cause pyrogenic or local reactions Physicochemical experiments indicated that to promote stability the fat particles and the protein of the emulsifying medium should have similar electrical charges. Promising preparations had been obtained with olive oil emulsified with either diluted blood plasma protein or a combination of dextran and soya bean phosphatides.

INTRACRANIAL SUPPURATION

In his presidential address to the Section of Neurology of the Royal Society of Medicine on October 6 Mr. JULIAN TAYLOR chose for his subject "Intracranial Suppuration." He remarked that almost since the advent of antiseptic surgery it had been known that certain varieties of intracranial abscess were amenable to treatment by drainage. Nevertheless, when in 1941 he took part in a discussion on this subject he had to speak of the treatment of abscess of the brain with some pessimism. Since then, thanks to penicillin, the outlook had changed considerably. It was often held that brain tissue had poor powers of resistance in relation to bacterial invasion, but it was doubtful whether that was true. A large proportion of cases of cerebral abscess had been successfully treated by some form of drainage, and it was possible that in many cases this treatment, although successful, was unnecessary, and that the minor procedure of aspiration might have been effective. Of the procedures for dealing with abscess of the brain the least destructive was aspiration of pus and the most destructive was excision, but the only possible deduction from the various results was that the brain itself must inherently have certain powers of resistance to suppurative infection.

In acute suppurative meningo-encephalitis, Mr. Taylor continued, the policy of awaiting localization and the formation of an anatomically thick and therefore palpable wall had many adherents, though it might well be that localization would not be sufficiently complete or rapid and the patient might succumb The discovery of penicillin had solved the problem of treatment when the causative organism was penicillin-sensitive, but it was important to ensure that the drug was so administered as to reach every infected tissue.

Mr. Julian Taylor then passed in review a number of cases of subacute and chronic abscess of the brain which he had treated. Before the war in his experience suppurative meningo-encephalitis had been almost invariably fatal. In 1948 a boy of 13 was brought into his hospital with this condition, and after some vicissitudes made a complete recovery, save for a residual epileptic tendency. No surgeon, he said, could have helped that boy without penicillin. He had many times excised brain abscesses in the past, but with penicillin available he thought this would seldom be necessary. There was now a wave of opinion in favour of excision almost as a routine, but, though he would not say that a cerebral abscess should never be excised, he thought that other methods would avail in most cases. The management of many of these conditions, which was previously a formidable procedure, had become almost simplicity itself. The neurological surgeon should offer humble thanks for the discovery of penicillin.

Sir CHARLES SYMONDS, in proposing a vote of thanks, said that it was tempting to imagine that the shades of great men of the past might be listening. He thought particularly of William Macewen, who 50 years ago announced to his sceptical colleagues that an uncomplicated cerebral abscess, diagnosed early, accurately localized, and operated upon, was one of the most satisfactory of all intracranial lesions.

Correspondence

Migraine

Sir,—May I suggest that Dr. G. S. Graveson's interesting article on retinal arterial occlusion in migraine (October 15, p. 838) may lead to unnecessary anxiety in people who suffer from attacks of migraine? In the first place it suggests that migraine is a disease, and that retinal arterial occlusion is a not very infrequent feature of it. I would strongly emphasize that migraine is not a disease but a *symptomatic syndrome*, as I have described it for many years in my *Diseases of the Eye*. Further, the statement that "there are numerous records of patients who have been left with a permanent homonymous visual-field defect after a migrainous attack" is liable to misinterpretation when one takes into account the very large number of people who suffer or have suffered from migraine. In fact one has to search the literature to find records of such cases.

The complete typical migrainous syndrome is so characteristic that it is unmistakable; but in mild attacks and in adults only parts may occur. In them, speaking from personal experience, the scintillating scotomata are most frequent; but headaches without scotomata can be recognized by intelligent sufferers as probably migrainous. It is very doubtful whether headache in the absence of scotoma or without any history of scotomata should be regarded as "migraine." On this criterion Dr. Graveson's Case 3 was not a case of migraine.

With regard to the vascular theory of migraine, Wolff and his colleagues advanced new confirmatory facts, but surely it has been the accepted theory for many years. The frequent association of other sensory phenomena in bad attacks—tingling and numbness of fingers and tongue, partial aphasia, etc.—shows that the vascular disturbance is not necessarily limited to the occipital cortex. It would not therefore be surprising to find similar arteriomotor changes elsewhere—e.g., in the retinal arteries—though of course the scotomata could not be attributed to them. I remember that many years ago the late Mr. Leslie Paton told me that he had watched the retinal vessels of a surgical colleague during an attack of migraine, but was unable to be certain that there were changes in calibre. Considering the differences of magnification due to optical conditions—refraction of the eye, distance of the ophthalmoscope from the eye, etc.—it would be almost impossible to be certain of any but gross changes.

On the other hand, it is certain that extreme and localized spasm of retinal arteries can occur and that they may precede "embolism" (which is usually thrombosis). I remember one such case under Sir William Lister at Moorfields which showed characteristic signs of "embolism" of a branch of a retinal artery; these disappeared during the course of the morning's observations.

Migraine is a very common complaint, and it implies the presence of a minor form of vasomotor instability. It is therefore not surprising that cases of retinal arterial occlusion and of permanent homonymous hemianopia should occur in migrainous subjects, but there is no doubt that relatively to the incidence of migraine they are rare. They naturally attract special attention owing to the characteristic visual disturbances of migraine. Would a physician pay much attention to a history of migra[illegible] in a case of hemiplegia?—I am, etc.,

J. Herbert Parsons.

[illegible]ngworm of the Scalp

Treat[illegible]nt

Sir,—We appre[illegible]ense of H. McCaw and endorse the Drs. J. Martin Beare [illegible]ment to of *x*-ray epilation in the emphasis they place upon [illegible]lt to es Our recent contribution treatment of ringworm of [illegible]he ag the article published (September 17, p. 626) was [illegible] which we introduced in the *Journal* of [illegible] scalp ringworm by preliminary *x*-ray epilation. We also stressed the significance of mechanical epilation in the ointment technique. In the paper we concluded that preliminary *x*-ray epilation, even when followed by simple ointment, still affords the quickest prospect of cure. We hoped we had made it clear that we regarded the *x*-ray technique as the 100% standard of cure and that with various fungicides and penetrating bases we have not exceeded a 75% rate of cure; the duration of treatment also is longer than that when *x*-ray epilation is used.

Our researches on the problem were begun during a spate of ringworm infections when some patients were waiting several months for their *x*-ray epilation. We had ample evidence of the ineffectiveness of the old and new fungicides in simple bases, but it was hoped that with the new emulsifying and penetrating agents better results could be obtained, and work on similar lines in the U.S.A. encouraged that hope. Our first results were disappointing, but with the elaboration of the technique described about three-quarters of the unselected patients were cured of their infection in two to three months.

Although the numbers of the successfully treated patients were small the results were sufficiently encouraging in view of our previous experience to justify their publication, and we hoped to stimulate further work on similar lines and in the meantime to offer an alternative method of treatment which could be employed with a fair measure of success when *x*-ray epilation was not available. Naturally the increased penetration of the fungicides, by virtue of the penetrating bases, carries more risk of skin irritation, and, contrary to the criticism expressed by Drs. Beare and McCaw, the reactions were reported. Also the duration of the disease was not given because a parent's fortuitous recognition of an obvious lesion is indefinitely related to the onset of infection. Apart from the spontaneous cure of *Microsporon* infection of the scalp which is usual at puberty we have seen no instances of spontaneous cure in our clinics nor any cures in patients using Whitfield ointment for three to six months while waiting for epilation. Drs. Barlow, Chattaway, and Whewell (October 15, p. 8[illegible] drew attention to several important factors requiring further investigation. While our results with phenylmercuric nitrate and salicylanilide suggested that there was nothing to choose between these two fungicides, it is probable that others with smaller molecules would more readily penetrate the hairs, and we have found that a dilute ammoniacal solution of copper sulphate with Crill No. 6 as a wetting agent gives comparable results. Although *x*-ray epilation alone has undoubtedly cured many cases of scalp ringworm in children, cure cannot be so certain as when followed by the daily use of fungicidal ointments, which also diminishes the risk of spreading infection.—We are, etc.,

H. Haber.

London, W.1.

Modern Trends in Radiology

Sir,—It is proper that from time to time we should pause to consider the efficacy of accepted procedures and prevalent tendencies in current practice, and therefore Dr. James F. Brailsford's address in Philadelphia (October 1, p. 724) is, as he says in his opening sentence, a stimulant to thought. It is regrettable that in his critical letter (October 15, p. 870) Dr. Peter Kerley, an official adviser to the Ministry of Health on mass radiography, should conclude his declamation with the remark: "It is unfortunate that such nonsense should be given space in a scientific journal."

Dr. Kerley's standpoint is not unassailable, and there are at least a minority who are thoughtfully concerned in regard to the use made in this country of the miniature radiography instrument. The technique which developed during the war for examining Service men and women is not necessarily the best for tackling the problem of tuberculosis in the civilian population. Hoffstaedt[1] pleaded that M.M.R. units should be used "at health centres, and should concentrate their attention on workers in hazardous industries, on contacts of known cases, and on suspicious cases with symptoms—i.e., the suspected rather than the unsuspected section of the population."

'SOLUTHIAZOLE' BRAND
TRADE MARK

neutral, soluble form of sulphathiazole

for the 'loading' dose

The rapid attainment of an effective concentration of the drug in the bloodstream is one of the first principles of sulphonamide therapy. 'Soluthiazole', a soluble form of sulphathiazole with a pH value of approximately 7, is undoubtedly the most effective medium for the 'loading' dose. It may be administered intravenously or intramuscularly without risk of local necrosis or tissue irritation and gives maximum blood levels within half an hour of intravenous injection. Following initiation with 'Soluthiazole', treatment may be continued by the oral administration of

trade mark **'SULPHATRIAD'** brand
compound sulphonamide

which combines maximal therapeutic activity with increased freedom from the risk of crystalluria.

'SOLUTHIAZOLE' *is supplied in boxes of 6 and 25 × 5 c.c. ampoules and in multi-dose containers of 25 c.c.*

'SULPHATRIAD' is supplied in containers of 25, 100 & 500 tablets and in 4 and 80 oz. bottles of suspension.

Our Medical Information Division will be pleased to send copies of the medical booklets 'Soluthiazole' and 'Sulphatriad' on request.

BRITAIN'S
STREPTOMYCIN

Glaxo Laboratories Ltd. recognise the responsibility placed upon them by the official announcement that their streptomycin products are generally available on prescription from November 1st, 1949. The manufacture of **Streptomycin Glaxo** (calcium chloride complex) is today on a substantial and expanding scale. No increased demand can be met at present, however, for **Dihydrostreptomycin sulphate Glaxo,** the production of which remains limited for the time being.

The need for exceptional care in the domiciliary use of streptomycin will readily be appreciated. Informative literature is available to the medical profession on request.

Both products available in cartons of ten vials, each vial containing material equivalent to 1 gram streptomycin base (1 mega unit) 70/- per carton. *Less usual professional discount.*

Introducing . . .

"MESONTOIN"

A marked advance in the treatment of

EPILEPSY

GRAND MAL, JACKSONIAN & PSYCHOMOTOR ATTACKS

Mesontoin can be administered in much larger doses than other anticonvulsants, thus opening the possibility of obtaining greatly increased control of epileptic seizures. The incidence of gum hyperplasia is reduced to the point of clinical insignificance; drowsiness is negligible. Mesontoin is tasteless and produces no gastric distress.

Clinical information available upon request to:—

SANDOZ PRODUCTS LIMITED
134 Wigmore Street, London W.1

The present tendency of M.M.R. units is to lead a nomadic life wandering among the factory populations of the more densely populated areas; with the supply of more mobile vans it is to be hoped that directors of these units will extend their peregrinations into less thickly populated areas. Even as a branch of preventive industrial medicine, however, the present use of M.M.R. is defective. (1) The early case of significant tuberculosis is probably off sick when the unit visits his factory. (2) Not all the factory employees are examined at any one visit. (3) It is rare that the unit succeeds in revisiting the factory at the yearly intervals which have been considered desirable. (4) When it does attain anything approaching regular repetitive visiting the value of this is substantially reduced by the diminishing number of employees who volunteer for re-examination on these visits.[**]

Occasionally an M.M.R. unit attempts a survey of the general public somewhere. In such instances the proportion of volunteers coming forward is often less than economically worthwhile; hence perhaps the infrequency of such sallies. If any serious attempt is to be made to mass radiograph a complete population of, say, 50,000 (excluding the unsusceptible age groups) the first requirement of an M.M.R. unit would be a highly trained publicity agent. Secondly, such a survey would necessitate a thorough speeding up of the rate at which examinees passed through the unit, perhaps attainable if a man did not have to strip to the waist and pass a row of formfilling clerks. Thirdly, two units working together would facilitate the sieving of such a general population during the limited time that the publicity management could keep the population keyed up. Fourthly, if successful, such an intensive survey ought completely to overload any existing clinic services, and these would have to be reinforced for the occasion.

The plight of M.M.R. calls for remedy in two opposite directions. Units must become much more mobile and flexible in the sort of work they do. Thus they should be ready to go off at short notice to a rural district devoid of electricity or suitable halls to investigate a relatively small group of people. Such a task need not be restricted to fluorography. As some units are doing at present under the aegis of the Medical Research Council, tuberculin-testing might well be linked with such work—and why not B.C.G. vaccination too? This would transform the unit from a not very efficient diagnostic weapon into the prototype tool for a real prophylactic attack on tuberculosis in this country. On the other hand the M.M.R. instrument, without its ponderous and elaborate equipage, would be a valuable addition to the armamentarium of the chest clinic. Many chest physicians in big towns are working some sort of "general practitioner x-ray service," and with a miniature radiography apparatus permanently installed such work could be vastly extended and contact work improved.

Dr. Kerley argues that the M.M.R. case of tuberculosis requires less time in a sanatorium than the case reporting to a chest clinic. Where is the evidence justifying such an important and dogmatic assertion? How long do the patients in the two groups have to wait before admission? How many of the M.M.R. cases admitted to a sanatorium really needed to go there at all? And what about the cases who ignore the early symptoms of chest disease because they had had a normal result a few months previously?

Perhaps the most important observation that Dr. Brailsford makes on mass radiography is the fact that these surveys have shown that 40 persons per 1,000 appear to have had fairly extensive disease and recovered from it without knowing of its existence. This teaches us that pulmonary tuberculosis is probably a great deal commoner than used to be thought, and also more benign. Yet tuberculosis damages the social and economic life of this country more than any other disease, and such a finding aggravates the difficult and crucial question of which are the cases of tuberculosis really needing treatment—a question which becomes more and more important as our diagnostic tentacles extend further and further into the normal life of the community.—I am, etc.,

Bradbury, F. C. S., *Lancet*, 1948, 2, 293.

SIR,—Now that Drs. Peter Kerley, A. Gordon Evans, and F. Kellerman (October 15, p. 870) have commented on some of the glaringly inaccurate generalizations made in Dr. James F. Brailsford's article (October 1, p. 724), may I be allowed to call the attention of general practitioners and of radiologists in particular to the relationship between mass radiography and Dr. Brailsford's "five omissions"? I know from personal experience that some radiologists hold similar views to his, and a remark recently addressed to me by a radiologist at a medical meeting, "But you know, Doctor, other things than T.B. show up in an *x* ray," summarizes the position of the chest physician in the eyes of some non-clinicians

The unit with which I am associated will continue to encourage the general practitioner to send cases and so to increase the present annual rate of 1,700 cases referred. The few figures given to support my statements are from this unit, being facts available to me, but it must be stressed that this unit is by no means exceptional.

Dr. Brailsford writes, "You may ask what evidence I have of these omissions. I believe you could obtain such evidence from the activities in many hospitals, but the strongest evidence is in the boosting of mass radiography." My comments on his "omissions" are as follows.

(1) His first "omission" is the failure to carry out clinical examination before radiology. This is impossible to rectify, by the nature of the work: but clinical examination is carried out if the history or radiograph indicates it. A history is taken from each person coming to the unit. Here it is advisable to remind practitioners that physicians, in contradistinction to Dr. Brailsford, do not diagnose activity by radiology alone.

(2) No individual can possibly have a better opportunity of learning the "bounds and appearances of the normal" than the physician in charge of a unit. He sees, probably, more normal films in a year than the radiologist who is not associated with a chest hospital sees in his lifetime. More than 43,600 miniature films were read here in 1948.

(3) Serial radiographs with clinical examinations are a routine, though a time-consuming one. Some 350 individuals are under such observation at the time of writing, apart from those referred for treatment.

(4) His next "omission," failure to appreciate that the onset of disease is not associated with immediate radiological change, is also untrue. Cases presenting themselves with a history of recent unexplained pleuritic pain are followed up regardless of negative radiological findings; some have been followed up for more than two years, some have developed disease, and all have been reassured by this evidence of interest in their welfare—a fact ignored by Dr. Brailsford.

(5) It is difficult to take seriously the statement that there is "a failure to realize that, though the disease has ceased its activity, the radiograph may show spectacular appearances even to the end of an apparently normal life." But if we are expected to take it seriously we can only speculate about the truth of some of the other sweeping statements made to the profession in the United States about clinicians in this country.

However much one may disagree with Dr. Brailsford about his "omissions" in relation to mass radiography, he was right when he said, "The best preventive medicine is that aimed at prevention, not that which is aimed at treatment of disease that could have been prevented." But this is, as yet, an ideal. Meanwhile all chest physicians especially will join him in his appeal for better homes, and if this letter does nothing but help to make those responsible for housing realize that tuberculosis is a social disease and that adequate housing is the first priority in its prevention it will have served its purpose.—I am, etc.,

Portsmouth. J. D. LENDRUM.

Sex Hormone Upset in Africans

SIR,—The very interesting article by Dr. J. N. P. Davies entitled "Sex Hormone Upset in Africans" (September 24, p. 676) contains the following passage: "From such cancerous livers [in Africans] carcinogenic substances have been isolated, probably sterols, as they have from non-cancerous African livers but not from the livers of Europeans or American

negroes. Failure of oestrogen inactivation would account for the finding of carcinogens in both cancerous and non-cancerous Bantu livers."

Dr. Davies has unhappily been misinformed. Des Ligneris' reported that in painting experiments tumours were produced on the skin of mice by extracts of Bantu livers but not by extracts of European livers, whether cancerous or non-cancerous. Steiner[2] found that extracts of livers, both from cancerous and non-cancerous negroes and whites in the U.S.A., were carcinogenic for mice. His figures are not very convincing for American negro livers, but he believes that the discrepancy was due to factors other than the potency of the extracts. In some recent papers[3,4] the present writer has shown that a considerable degree of carcinogenic activity can be detected in the sterol fraction obtained from liver, lung, kidney, and muscle of cancerous and non-cancerous Europeans, and from a variety of other biological sources—for example, from cow's milk and from the spinal cord and brain of cattle (i.e., commercial cholesterol).

However, these facts do not lessen the interest of the other evidence that Dr. Davies has collected in favour of the view which has been put forward by earlier investigators, that malnutrition may cause an aberration of liver function which increases the incidence of some forms of cancer.—I am, etc.,

The Osler Family

SIR,—In view of the fact that this is the centenary year of the birth of Sir William Osler it seems opportune to correct an error which often recurs in medical biographies, that Sir William Osler and Sir Jonathan Hutchinson had common collaterals in Lincolnshire. As Dr. W. W. Francis, librarian of the Osler Library, McGill University, Montreal, pointed out in the Osler commemoration number of the *British Medical Journal* (July 9, p. 45), the connexion, if any, between the two families is between a Lincolnshire Hutchinson family and that of Lady Osler.

Hutchinson-Revere (Osler) Pedigree

John Hutchinson[1] Mayor of Lincoln 1556, 1564; b. Lincoln 1515, d. Lincoln 1564.	*m.*	Anne b. ?, d. Lincoln 1586
Edward *Mercer of Alford*; b. *Lincoln* 1564, d. Alford 1631.	*m.*	Susannah b. England, d. Wells, Maine, U.S.A., 1644.
William b. Alford 1586, d. Newport, R.I., 1642.	*m.*	Ann Marbury[2] b. Lincs. 1591, d. Connecticut 1643.
b. Alford 1613, d. Marboro. Mass., U.S.A., 1656.	*m.*	Katherine Nainby daughter of Councillor Nainby, Ipswich.
Elisha b. 1640, d. 1717.	*m.*	Elizabeth (Clark) widow of John Freak; b. Dorchester 1642, d. Boston, U.S.A., 1713.
Edward b. Boston, U.S.A., 1678, d. Boston 1752.	*m.*	Lydia Foster b. Boston, U.S.A., 1686, d. Boston 1748.
Elizabeth b. Boston, U.S.A., 1731, d. Milton, U.S.A., 1798.	*m.*	Rev. Nathaniel Robbins b. Cambridge 1726, d. Milton 1795.
Edward Hutchinson Robbins b. Milton 1758, d. Boston, U.S.A., 1829.	*m.*	Eliza Murray b. Wilmington 1756, d. Cambridge, U.S.A., 1837.
Mary b. Milton 1794, d. Boston 1879.	*m.*	Joseph Warren Revere[3] b. Boston 1777, d. Canton 1868.
Grace Revere b. Boston 1854, d. Oxford 1928.	*m.*	Sir William Osler b. Canada 1849, d. Oxford 1919.

[1] Hill, J. W. F., "Three Lists of Mayors of Lincoln," *Ass. arch. Soc. Rep.*, p. 30. See also Maddison, A. R., *Lincolnshire Pedigrees*, 1903.
[2] This is Anne (Marbury) Hutchinson, the Preacher (*Dict. Nat. Biog.*), massacred at Hell Gate, N.Y., by Indians in 1643 with all, except the eldest (Edward), of her 19 children.
[3] Grandson of Paul Revere, the American patriot.

For the benefit of future students of medical biography the above pedigree will illustrate the connexion. Any relationship between this Hutchinson family and that of Sir Jonathan Hutchinson, which originated in South Lincolnshire, around Gedney, has not been traced.—I am, etc.,

Burnley, Lancs. A. E. WALES

Myxoedematous Madness

SIR,—Dr. R. Asher's letter (October 8, p. 818) is unexceptionable save for some minor misunderstanding of my views; I am glad to find that he is no longer maintaining his unrestrained opinions, represented, for example, by, "Myxoedema is one of the most important . . . and one of the most frequently missed causes of organic psychoses," and, "The fact that recorded cases of myxoedema psychosis have closely resembled paranoia schizophrenia, melancholia, or other orthodox psychoses does suggest that the common psychoses . . . may turn out to be not diagnoses in themselves but manifestations of underlying organic disease." The main object of my original letter has now therefore been gained.

I regret that my letter (September 24, p. 706) has had another and unwished-for effect; I see from subsequent correspondence that it has caused hurt. I did not realize that it could hurt anyone so much as it has evidently hurt Dr. Martin Roth (October 15, p. 871). For this I must apologize.—I am, etc.,

Sutton, Surrey. E. B. DAVIES

SIR,—I am saddened, but not surprised, that there could be any objection to the saner perspective into which Dr. E. B. Davies's letter (September 24, p. 706) put the paper by Dr. R. Asher entitled "Myxoedematous Madness" (September 10, p. 555). Psychoses commonly occur with major or minor "physical" disorders which contribute to the stresses disintegrating the personality, so that every attention to physical health is rationally part of their treatment.

To suggest, however, that there is an entity "myxoedematous madness" as distinct from, say, rheumatic madness, acute haemorrhagic madness, or pulmonary tuberculous madness, or that it has a more specific response to appropriate treatment requires more evidence than that supplied by Dr. Asher. He presents 14 cases of psychosis. In at least six the mental state was that of clouded consciousness, which is very commonly associated with befuddled and perplexed behaviour, as, for example, in high fever or uraemia. Significantly, two of these were moribund (Nos. 4 and 13), and, of the others, three (Nos. 5, 6, and 10) responded immediately to thyroid as they regained consciousness, while Case 9 responded more slowly as there was an intervening head injury and the dose of thyroid was too small at first to control the myxoedema.

This leaves eight cases with a psychosis amounting to something more than sensorial clouding, and of these three failed to respond to thyroid. This hardly permits the assertion that myxoedema is "one of the most important" causes of organic psychosis. Indeed no other conclusion is legitimate than that like many other generally debilitating illnesses (tuberculosis, cancer, influenza, severe anaemia, and high fever), it may produce clouding of consciousness or contribute decisively to the stresses leading to disintegration of the personality which may or may not be reversible if physical health is restored.—I am, etc.,

Virginia Water, Surrey. H. BOURNE

Treatment of Early Syphilis

SIR,—In order to avoid misconception, it would appear that several of the points raised in the annotation regarding the treatment of early syphilis (September 24, p. 694) require clarification. It must be stressed that our results cannot be described as "appreciably worse," as they are not strictly comparable with those of McElligott, Jefferiss, and Willcox,[1] as the latter reported figures uncorrected by any actuarial method for default, etc. Unfortunately it is impossible for me to check the reference, being overseas, but if memory serves me aright the same applies to the other paper quoted in the annotation

Secondly, it is pointed out that the cumulative relapse rates, as distinct from the treatment-failure rates (sero-resistance), reported by us were the actual calculated cumulative rates of relapse obtained from the crude figures shown by means of an actuarial formula. They were only affected by a "laudable desire to take no chances with patients whose follow-up is likely to be jeopardized by an early return to civil life" in so far as possible reinfections were regarded as being relapses.

The behaviour of the serum reactions in early syphilis and their significance are fully appreciated. However, at the time when the form of treatment discussed in our paper was first commenced (1946) it had been decided to re-treat all sero-positive cases in which the reaction had not become negative at the end of four months as an added safeguard. Further, this can hardly be any more deemed to show "too blind a faith in blood tests" than would have been a hopeful reliance in a falling titre.—I am, etc.,

The Acute Throat

SIR,—I read Dr. T. Anderson's paper on the acute throat (October 15, p. 860) with interest and enjoyment, and I am sure that many practitioners besides myself will be thankful for such a clear summary of the diagnostic problems involved. When, however, the subject of treatment is considered, one cannot help feeling that Dr. Anderson is approaching the subject from the standpoint of the fever hospital and not that of general practice.

Streptococcal tonsillitis is one of the commonest ailments in general practice, and for its treatment we are given the alternatives of parenteral penicillin or therapeutic nihilism concealed by a screen of household remedies. I am entirely in agreement with Dr. Anderson that penicillin lozenges are useless; but four-hourly injections of penicillin are seldom feasible in general practice, and it would not be possible in present-day circumstances to obtain a hospital bed for every case of streptococcal tonsillitis of moderate severity. Why, then, are the sulphonamides mentioned only to be condemned? Dr. Anderson condemns them on two grounds—their supposed inefficacy and their possible toxic effects.

In common with the vast majority of general practitioners I have treated streptococcal tonsillitis with sulphonamides with complete satisfaction to myself and my patients. If, as so frequently happens, one sees a patient with an acutely inflamed sore throat and a high temperature (due to β-haemolytic streptococci), and finds that after 48 hours' treatment with sulphonamides the temperature is normal and the local condition resolving, it is surely not unreasonable to suppose that the use of sulphonamides has had something to do with the result.

I am not in a position to quote my "controls," but those who are old enough to remember the pre-sulphonamide era cannot be uninfluenced by the memory of the more protracted course of tonsillitis in those days and the higher incidence of complications (such as quinsy). Statistics can no doubt be made to prove anything, and fortunately I have none with which to bemuse the minds of your readers. Nevertheless I feel sure that my fellow practitioners will bear me out when I say that the efficacy of sulphonamides in streptococcal tonsillitis is entirely comparable to that in acute pneumococcal pneumonia, a condition in which, so far as I know, nobody doubts their efficacy. One might go even further and say that if a case of acute streptococcal tonsillitis does not rapidly respond to sulphonamides one should suspect some complication or a mistaken diagnosis. Recently I had such a case which did not respond, and further investigation showed that it was in fact a case of glandular fever.

Coming to the other objection to sulphonamides—i.e., their toxicity—one must acknowledge that there are occasional cases where the use of sulphonamides does harm; but if one of the more recent sulphonamides is chosen and adequate precautions are taken with regard to dosage and fluid intake this risk is surely negligible. I write this letter in the hope that younger practitioners will not be deterred by Dr. Anderson's scepticism from treating their cases of streptococcal tonsillitis with such a simple and efficacious remedy.—I am, etc.,

Oxford. A. M. RICHARDS.

SIR,—In his article on the acute throat (October 15, p. 860) Dr. T. Anderson makes the statement that the efficacy of the sulphonamides "has never been convincingly demonstrated." I am quite certain that thousands of practitioners through long clinical experience are convinced of the efficacy of, in particular, the more recent sulphonamides. Any doctor in practice in pre-sulphonamide days will recall the anxiety he felt over many cases of severe streptococcal tonsillitis, and will compare it with his peace of mind over similar cases now dealt with effectively by the sulphonamides.—I am, etc.,

Dagenham, Essex. J. FINER.

Trichostrongylus Infestation in South Persia

SIR,—Conditions are favourable for ankylostomiasis in Abadan; not the reverse as claimed by Dr. Ian S. Stewart (October 1, p. 737). Anaemia is probably still frequent in Abadan. Damp soil suitable for the hatching and larval moults of *Ankylostoma* species is common in the riverine hinterland, and the inhabitants habitually go about near their homes with bare feet.

Strongylus subtilis Looss 1895 was found in 17 persons in Abadan in 1934 (*Ann. Med. Rep. A.I.O.C.*, 1934, p. 61) and in 16 persons in 1933 (*Ann. Med. Rep. A.I.O.C.*, 1933, p. 67). *Strongylus subtilis* is a synonym for *Trichostrongylus colubriformis* Giles 1892 and for *Trichostrongylus orientalis* Jimbo 1914. According to Faust (*Human Helminthology*, 1929, Philadelphia, p. 390) *Trichostrongylus orientalis* is easily cleared from the human system by doses of carbon tetrachloride, as for ankylostomiasis. Human infestation by *Trichostrongylus* is due to raw consumption of plant stems and leaves contaminated with the faeces of infected animals.

Dr. Stewart states that 70% of the inhabitants (of South Persia) carry the "harmless" sheep parasite *Trichostrongylus*, 25% carry the common *Ascaris*, and that other helminthic parasites are rare. This statement is not correct. In the *Annual Medical Report* for 1933 of the Anglo-Iranian Oil Company (pp. 41–3) I described 11 varieties of helminthic parasite, all of which were common among the indigenous human population.

The modern Abadan may be better than the "old town." There was much room for improvement; but Abadan, old or new, is not representative of the rest of South Persia: one may fervently hope it never will be. It is possible that conditions in Abadan have changed, so that the life cycle of *Trichostrongylus* is much facilitated while that of *Ankylostoma* is correspondingly depressed by increasing urbanization together with bad sanitation. However widely the "town" sprawls, animal, vegetable, and human life in the secluded and shady fringes of the Shatt-el-Arab continue under conditions that have changed hardly at all since Alexander's admiral brought part of his India expedition by boat through the Persian Gulf and up the conjoined "three great rivers" of the Old Testament and won the battle of Arbela in 331 B.C.—I am, etc.,

Epping, Essex. FRANK MARSH.

Gangrenous Intussusception

SIR,—The account by Mr. J. A. Kerr (September 10, p. 580) of a successful resection of small intestine for gangrenous intussusception in an infant of 6 months prompts me to record a gangrenous intussusception cured by hemicolectomy (and end-to-end anastomosis), the patient being a boy only 3 months old. In a search of the literature I have been unable to find any record of recovery in so young a patient when it has been necessary to resect the proximal half of the colon. Dennis[1] describes a success in an infant of 39 days, but in this case it was necessary to resect only the small bowel.

The infant was 12 weeks old when transferred to the Royal Salop Infirmary on October 6, 1948. There was a history of

10 days' persistent vomiting. On the day of admission he passed blood per rectum for the first time. On admission the baby was deathly pale and grossly dehydrated, with sunken fontanelles and the skin lying in folds. The pulse was almost imperceptible. A sausage-shaped tumour could be felt lying transversely above the umbilicus.

A continuous intravenous saline was given at the ankle and gastric suction begun. As the child was apparently dying, operation was decided upon without much optimism and begun two hours after admission. The patient still looked palely cyanotic and the pulse had not improved. Procaine (1%) was used as a local analgesic, supplemented by ether and gas-and-oxygen given by Dr. Harker. A gangrenous ileo-colic intussusception was found, the apex being near the splenic flexure, and it was possible to reduce it only as far as the hepatic flexure. In doing this a tear was made in the gangrenous ascending colon, and there was some faecal contamination. A resection was done of the lower ileum, caecum, ascending, and part of the transverse colon, and an end-to-end anastomosis performed, using a single piercing Connell catgut suture. Penicillin (10,000 units) was given four-hourly after the operation.

On the day following the operation the bowels moved twice. Three days later the baby was vomiting all feeds, although there was but little abdominal distension. Intravenous saline was recommended, but vomiting continued for five days. "Eumydrin" was then given before the feeds, and the vomiting ceased. From then on recovery was rapid, and the infant was discharged fit after 31 days. He was seen again on September 23, 1949, and appeared to be normal in every respect.—I am, etc.,

Shrewsbury. D. LINCOLN LEWIS.

Cutaneous Horn of the Nose

SIR,—In the *Journal* of September 17 (p. 635) Dr. V. R. Tadros reported a case of cutaneous horn. The following particulars of a cutaneous horn of the nose may be of interest—even in an extremely busy out-patient clinic it is very rare to come across such a case.

A man, aged 61, came to the out-patient department with a horny mass growing from the right side of the nasal septum at the muco-cutaneous junction. The length of the horn was 2¾ in. (6.9 cm.), and its circumference at the base was 1¾ in. (4.4 cm.). The patient had had this growth for the last ten months, and whenever it caused him annoyance he used to cut some of it off. The growth was removed by Mr. F. B. Gilhespy, who has kindly given me permission to publish the case. My thanks are due to Mr. Lee, the photographer, and to the patient for co-operation.

—I am, etc.,

Birmingham W. A. MALIK.

The G.P. and E.C.T.

SIR,—Time and again correspondents who specialize in nervous and mental diseases suggest that in E.C.T. they have a means of treatment which in almost all cases in which it is used is completely satisfactory in short-term and long-term results. Would any large number of general practitioners who have the aftercare of such patients agree that this degree of complacency is justified?

My own experience is that patients are returned to my care wearing, as it were, a brittle mask of cheerfulness. After an interval, which too often is regrettably short, this mask is shattered and once more one starts the dreary business of ringing the changes on the bromides, barbiturates, and chloral hydrate, and the exhausting performance of trying to infuse into the patient some moral force, glibly referred to by our more learned colleagues as "reassurance." I conclude by stating that my patients have been treated at some half-dozen different centres.—I am, etc.,

Launceston, Cornwall. DONALD M. O'CONNOR.

Medical Services of the Armed Forces

SIR,—My article on the above subject (October 1, p. 751) was much abbreviated from the original. I therefore wish to emphasize a few special points.

1. Efficient Regular specialists in curative medicine can be maintained in the future only by markedly increasing the field of clinical work. Owing to the demands of modern medicine curative specialists must be full-time. They should not be looked upon as future administrators outside their particular specialty.

2. In preparation for a future war a strong nucleus of Regulars trained in medical administration is essential. Such work will be much more efficiently performed if these officers have previously had the following professional training: (*a*) a practical apprenticeship in all or nearly all the special departments of a Service hospital, and (*b*) a practical apprenticeship in preventive medicine.

3. Scope for Regulars to train as curative specialists may not (in the opinion of some) be essential to the Services, but without it recruitment will never be satisfactory and the prestige of the Regular doctor will be greatly reduced.—I am, etc.,

E. A. SMYTH,
Major, R.A.M.C

POINTS FROM LETTERS

Rheumatoid Arthritis and Herpes Zoster

Dr. E. SAKOSCHANSKY (Southampton) writes: During the severe winter weather of 1947 a boilermaker aged 55 developed a sharp attack of rheumatoid arthritis. This persisted: he could not close his fingers, he walked like an old man, and he was very tired at the end of the day's work. On June 23, 1949, he suddenly found that his rheumatism was much better, and on June 26 the first crop of herpes-zoster vesicles appeared, on the right side, in the distribution of the ophthalmic branch of the right trigeminal nerve. On July 5 he could close his hands, he walked downstairs two steps at a time, his walk was that of a young man, and he could "dance" on his toes. The only sign of rheumatoid arthritis was some swelling of the third and fourth fingers of the right hand, but there was no pain in those fingers. On July 6 he complained of just a little "kink" in his ankles, which he attributed to the change in the weather, but by August 13 the rheumatism was "not so good." The rheumatoid condition is perhaps at the time of writing not so severe as before the herpetic eruption; he does not look so anaemic, but he is still unable to think of work. His hopes were high during the early days of the herpetic illness; he was very disappointed that the rheumatism had come back. This case emphasizes the important fact that rheumatoid arthritis is a reversible disease, and it is tantalizing to me that I cannot reverse it in my patient. Perhaps it would be possible to devise indirect methods of attacking the disease of rheumatoid arthritis whilst supplies of "cortisone" or cortisone-like bodies are synthesized.

Weight-reducing Diet

Miss C. M. M. ADAMSON (Out-patient Dietitian, St. Bartholomew's Hospital) writes: I have read with interest the article by Dr. H. L. Marriott entitled "A Simple Weight-reducing Diet" (July 2, p. 18) and the letter by Dr. E. Domany (September 24, p. 709). Little can be done without the close co-operation of the patient. What is the best method of securing and preserving this salient feature? The suitably qualified dietitian, with her specialized training, can greatly assist the physician or surgeon to achieve the desired results. Her approach is necessarily rather different from that of the physician, particularly in a busy out-patient department. Experience confirms my opinion that her individual interest and constant encouragement are of vital importance. The planning of the diet in the presence of the patient, giving due consideration to his or her social circumstances, occupation, normal arrangement of meals, etc., is then possible. Complete freedom regarding low calorie foods is permitted normally, and patients are assured that they need never feel "starved" or empty. Monthly visits and interview with the same dietitian are arranged, and patients are advised to weigh themselves weekly. Drastic diets such as those suggested by Dr. Domany are surely unnecessary from a social aspect and contraindicated nutritionally.

'CETAVLON'

brand

CETRIMIDE

'Cetavlon' is a synthetic cationic detergent consisting essentially of cetyltrimethylammonium bromide, a voluminous white powder, readily soluble in water. The solution has high surface activity and exhibits excellent detergent, emulsifying and bactericidal properties. It is of low toxicity and relatively non-irritating to skin and mucous membranes.

The strength of solution usually employed is 1%. The main indications are: pre-operative skin sterilisation; the cleansing and disinfection of wounds and burns; the removal of scabs and crusts in skin diseases such as impetigo and the cleansing and disinfection of hospital vessels, sickroom utensils, etc.

'Cetavlon' powder is issued in containers of 50 and 500 grammes and 2 kilogrammes, and in envelopes, containing 5.7 grammes, packed in boxes of 25 and 100.

'Cetavlon' concentrate (20%) is in containers of 100 c.c., 500 c.c., and 2 litres.

'Cetavlon' Tincture 0.5% is in bottles of 100 c.c. and 500 c.c.

'PERNIVIT' FOR CHILBLAINS

-Tablets of Acetomenaphthone B.P. and Nicotinic Acid B.D.H.

'Pernivit' is a scientifically formulated preparation combining nicotinic acid and acetomenaphthone (vitamin K analogue), both of which used separately have proved to be of considerable value in the treatment of chilblains. There is evidence that 'Pernivit' combines the effectiveness of both; it utilises the vasodilator properties of nicotinic acid and the effect of vitamin K in maintaining normal blood coagulability and vascular permeability. Itching and inflammation are quickly relieved following the administration of 'Pernivit.'

'Pernivit' is available in bottles of 50 and 500 tablets.

Literature and samples will be forwarded on request

TELEPHONE: CLERKENWELL 3000 TELEGRAMS: TETRADOME TELEX LONDON

Prvt/E/637

PREGNAVITE

a single* supplement for safer pregnancy

CLINICAL USES

To improve the nutritional state where circumstances prevent consumption of all the protective foods required; to prevent hypochromic anæmia.

Indications in the history of previous pregnancies: toxæmia, previous premature births, inability to breast feed and dental caries.

* The recommended daily dose provides: vitamin A 2,000 i.u., vitamin D 300 i.u., vitamin B_1 0.6 mg., vitamin C 20 mg., vitamin E 1 mg., nicotinamide 25 mg., calc. phosph. 480 mg., ferr. sulph. exsic. 204 mg., iodine, manganese, copper, not less than 10 p.p.m. each.

Obituary

SIR MAURICE CASSIDY, G.C.V.O., C.B., M.D. F.R.C.P.

Sir Maurice Cassidy, who died at his home in London on October 22 at the age of 69, was consulting physician to St. Thomas's Hospital. He had been physician-in-ordinary to the King since 1937 and was one of the outstanding cardiologists in this country.

Maurice Alan Cassidy was the eldest son of the late Dr. D. M. Cassidy, C.B.E., medical superintendent of the Lancaster Mental Hospital. He was born at Lancaster on February 29, 1880, and after leaving school there he went to Clare College, Cambridge, of which he was a scholar. He took a first class in both parts of the Natural Sciences Tripos. At St. Thomas's Hospital he was a student of unusual ability, and one of Dudgeon's earlier pupils as a clerk in the clinical laboratory. He qualified in 1905, graduated M.B., B.Ch., a year later, and proceeded M.D. in 1909. He was a house-physician at St. Thomas's Hospital, resident assistant physician from 1908–10, and later medical registrar. It was at this time that he decided to turn away from the academic life which the offer of a fellowship at Clare afforded and settle in London. He held a Salters' Company research fellowship in 1907, 1912, and 1913. In 1913 he was elected F.R.C.P. and joined the honorary staff of St. Thomas's Hospital. In 1914 he gave the Goulstonian lectures of the Royal College of Physicians.

[Russell & Sons

During the first world war Cassidy spent two years in the Army in this country and in France, acting as physician to No. 2 Anglo-Belgian Fever Hospital at Calais. Then in 1916 he was invalided out with pulmonary tuberculosis, and it was nearly two years before he was fit enough to return to work. His courage in facing this setback roused the admiration of all who knew him. His own experience then may also have had something to do with his remarkable kindness and sympathy in handling sick people. Returning to active practice he rapidly built up a considerable reputation as a consultant and as an authority on disease of the heart. Those were the early days of clinical electrocardiography, and he soon established himself as an expert in the new methods of accurate diagnosis.

It was in 1929 that Cassidy gave up his appointment, which he greatly valued, as chief medical officer to the Metropolitan Police, and on this occasion he was awarded the C.B. Shortly afterwards, in 1932, he received his first appointment at Court as physician to His Majesty's Household, and since then he had served successive monarchs as physician extraordinary, and later became physician-in-ordinary to His Majesty King George VI. He was created K.C.V.O. in 1934, and after attending the King during his illness earlier this year he was promoted G.C.V.O. This promotion was gazetted just after an accident in April when he and Lady Cassidy were both seriously injured. As Sir Maurice Cassidy was too ill to attend the formal investiture, the King paid him the unusual honour of driving to his house in Montagu Square and performing the ceremony there, as recently as October 10.

Sir Maurice Cassidy retired from the active staff of St Thomas's Hospital in 1939, but within a month the outbreak of a new and greater war interrupted his retirement, and he returned to serve the hospital, carrying throughout the war years a burden that few younger men could have borne better. In the wards and the out-patient department he spent many hours each week, and his example was a great source of strength to those who were working with him. Only in the autumn of 1945 did these day-to-day activities come to an end, and only then was full effect given to the resignation from the active staff which ought to have taken place normally in 1939.

Many distinctions came his way. He was president of the Royal Society of Medicine in 1946–8 and of the British Cardiac Society. At the Royal College of Physicians he held the offices of examiner, councillor, and senior censor. He delivered the Harveian oration in 1946, taking as his subject the incidence of coronary disease. He was physician to the Lord Mayor Treloar's Cripples Hospital at Alton, and consulting physician to the King Edward VII Sanatorium, Midhurst, and the Children's Heart Hospital, West Wickham. In July of this year he was elected an honorary fellow of his old college at Cambridge. His writings were almost entirely concerned with cardiology, apart from his co-authorship with Mr. J. E. Adams in 1913 of a book on acute abdominal diseases. He contributed many papers to this and other journals on such subjects as hypertension, coronary disease, the treatment of cardiac cases, and carotid body tumour.

Quiet and unobtrusive, Sir Maurice Cassidy always appeared diffident. He was a man of innate modesty, and had a deep sincerity and sympathy of manner which made him universally beloved. He had a dry, ironical sense of humour, but in later years his natural shyness and diffidence grew more obvious. This and a certain aloofness must have made it difficult for him to realize how strong was the affection felt for him by his colleagues and his students. On all those who worked for him and with him, his was the influence of the good physician.

He married in 1918 Elise, youngest daughter of Frederick Relfe. There were no children of the marriage.

Dr. J. P. Hedley writes: The death of Maurice Cassidy has removed from us a great physician, but it is not as a physician but as a man and a friend that I am writing. Perhaps the most outstanding of his characteristics were his courage, his kindness, and his courtesy. During his professional life he had several prolonged periods of ill health which might have altered his whole future, but he faced all his difficulties with wonderful courage and determination to overcome them. When first it seemed possible that his health might make it unlikely that he would be able to stand the strain of hospital work in London an offer was made to him to return to Cambridge as a Fellow and teacher; but his heart was set on becoming a consulting physician, and he felt himself unable to accept the offer.

His kindness was as great as his courage. If any friend needed his help he was not only willing but anxious to do his utmost for him, even if this added much to an already hard day's work. I know of many cases where he went long distances out of London on several occasions to help in the treatment of some friend or doctor. His charming courtesy endeared him to his patients, the students, and nursing staff at St. Thomas's as well as to his colleagues.

He was considerate in his dealings with everybody, and I do not remember his ever making a harsh remark about anyone. He was firm in his opinions and was a good chairman of the staff committee of the hospital.

I first knew him when he came to St. Thomas's Medical School from Cambridge, where he had had a distinguished career. He was modest and unassuming, and in spite of his great attainments and success in later years he retained his charming modesty and simplicity to the end of his life. After his serious accident in April he suffered a great deal of pain, but retained his sense of humour in spite of all and was most amusing in describing the curious dreams he had, apparently as the result of the drugs he was given, which often seemed real long after he was awake. While still in hospital he was elected to a fellowship at Clare, his old college that he loved so well. Nothing, I am sure, could have given him greater pleasure and satisfaction, and he regarded it as great an honour as any man could receive. He went home after being in hospital for more than three months in high hopes of getting back his health and strength, but he was soon attacked by a disease, unconnected with his accident, which was certain to prove fatal. He received the news of this with his characteristic courage.

To me, like very many others, Maurice Cassidy's death has caused the deepest sense of loss and sorrow.

CHARLES OLIVER HAWTHORNE, M.D., F.R.C.P. LL.D., D.Sc.

A rare figure has passed away in Charles Oliver Hawthorne, who died on October 24 at the age of 91. He was for long the Nestor of the British Medical Association Council, but also the Rupert of debate, if one may so bring together the suggestion of age and youth. Dr. Hawthorne was always reticent about personal matters, and for that reason he was not really well known even to the men with whom he worked in close relationship. Although he had touched many sides of public life and medicine, his speeches rarely or never had an autobiographical tinge. But he did respond some years ago to an entreaty from a former colleague at Headquarters for some material for a biography which it was hoped would remain in the pigeonhole for another generation at least. From this material the surprising fact emerged that he was born as far back as 1858. Few who saw his four-square figure, immaculately dressed in grey frock coat and perfectly creased trousers, and with a grey "silk hat" to match, his face aglow with his own humorous and kindly outlook on life—a brother Cherryble, but far more intellectual, and with a sardonic touch about the bristling eyebrows—would have supposed that he was anywhere near fourscore. His speeches at the age of 80 were as full of wit and wisdom as ever.

[Haines, London

Hawthorne was a Glasgow man, and not until middle life did he set out upon the well-worn track from Scotland to London. He graduated M.B., C.M. from the University of Glasgow in 1884, with first-class honours and the Brunton Memorial Prize as the most distinguished medical graduate of the year. Fifteen years later he took the M.D., again with first-class honours and the gold medal. He had already taken the F.R.F.P.S.Glas. by examination. It must have been a great pride to him to receive, 30 years afterwards, the Hon. LL.D. of his own university, a bestowal followed soon afterwards by the Hon. D.Sc. of Manchester and the honorary fellowship of the Royal Academy of Medicine in Ireland.

For the first ten years of his professional career he was university assistant to the professor of practice of medicine, Glasgow, and clinical tutor in Sir William Gairdner's wards, Western Infirmary. Later he became assistant physician in the same hospital and lecturer on materia medica and therapeutics at Queen Margaret College of the University. Later still he was examiner for the Universities of Aberdeen, Edinburgh, and Glasgow, and for the Scottish Conjoint Board. His early contacts with medical society life were, of course, also in Glasgow, where he held office at one time as honorary secretary and editor of the Royal Medico-Chirurgical Society and as president of the Glasgow Southern Medical Society.

Having gained all the academic prizes that his native city had to offer, Hawthorne became a consulting physician in London. He was also for a time medical director and afterwards chairman of council of the Medical Graduates College and Polyclinic in Chenies Street—an early and gallant effort to provide such postgraduate facilities as are now arranged by the Fellowship of Medicine and the British Postgraduate Medical School at Hammersmith. Among the London hospital appointments which he held were those of physician (later consulting physician) to the Hampstead and North-West London General Hospital, the Royal Waterloo Hospital for Children and Women, the Central London Ophthalmic Hospital, and the Central London Hospital for Diseases of the Nose, Throat, and Ear. He was elected a Fellow of the Royal College of Physicians of London in 1921.

From time to time Hawthorne employed his pen to excellent purpose. Some of his books date back to his Glasgow days. His handbook on *Galenical Preparations of the "British Pharmacopoeia"* was published in 1895; his *Forensic Medicine and Toxicology* ran through two editions in the 'nineties, and was again published, largely rewritten, in 1912. In 1912 also appeared his *Studies in Clinical Medicine*, a volume of nearly 500 pages, and in 1928 came a little work entitled *Short Essays on Medical Topics*, in which, with many shrewd observations, he set out his views on a variety of subjects, often touching his favourite territory of medical ethics. Even apparently trivial subjects he could illuminate with much wisdom. The "topics" included the telephone in medical practice; the teaching value of lectures; the relation (always a very dubious one in his eyes) of doctors to the lay press; the choice of names for diseases and disease phenomena; secret terms in physicians' prescriptions; the sudden greying of the hair. Even the baby-show—"as valueless as it is vulgar"—made a chapter, and there was also included an address he gave from a pulpit on Hospital Sunday. He also made numerous contributions on clinical medicine and medical ophthalmology to the medical journals, and these, like his papers read before scientific societies, and indeed his extempore speeches, were perfectly polished, the outcome of a singularly erudite mind and of a master of language.

Hawthorne's work for the British Medical Association brought him into closer contacts with his profession. None exceeded him in loyalty or in delight in many sides of the Association's work. He was unexcelled in its forum. When he went to the platform the whole tenor of debate was lifted. He never studied brevity in

speech, but his audience, admiring his style, forgot his length, and if the time limit ran out there were always calls to him to continue. His speeches were also of the kind that swayed votes. One noteworthy occasion—though the subject was relatively unimportant—was at the Representative Meeting at Bournemouth, when his eloquence secured rejection of the Council's recommendation for the recognition of chiropodists, and four years later, when the proposal came up again, he attacked it with unabated vigour.

Unlike some orators, he was also a good committee man. At one time or another he was a member of thirty committees or subcommittees of the Association, ranging over such subjects as postgraduate courses, medical ethics, lunacy law, charities, psycho-analysis, the *British Pharmacopoeia*, medical education, osteopathy, and even regulations and standing orders, in which last he found sometimes quite a perverse delight. His work on the Ethical, Science, and Charities Committees was of great importance and value, and his long chairmanship of the Library Subcommittee earned him the gratitude of all who used the Association's Library. One of his achievements on which he himself looked back with special pride was his action in getting established the Sir Charles Hastings Clinical Prize. Another was the part he took in placing the Association Charities Fund in a position, not of rivalry, but of co-operation with the Royal Medical Benevolent Fund and Epsom College. He served as representative of the Association on the committee of management of the R.M.B.F. and often took the chair, and his interest in medical charities went very deep.

Other work of his included membership of the statutory advisory committee under the Therapeutic Substances Act, to which he was nominated by the B.M.A.; he was also its nominee on the advisory committee on international certification of causes of death, and he represented the Royal College of Physicians on the Departmental Committee on the Optical Practitioners Bill. He did much to help in the establishment of the Consultants' Board for London, and was its first chairman. At Annual Meetings of the Association he was vice-president of the Section of Medicine in 1922 at Glasgow and of the Section of Pharmacology and Therapeutics in 1936 at Oxford; on two occasions he was vice-president of the Section of Medical Sociology, and president of that Section at the Dublin Meeting in 1933. Another abiding interest of his was the People's League of Health, where he was—and the phrase is a just one—Miss Olga Nethersole's "right-hand man" for many years.

His membership of the British Medical Association extended back over more than half a century, to 1888. He had been chairman of the Marylebone Division and president of the Metropolitan Counties Branch. He attended every meeting of the Representative Body, save one, from 1915 to 1938, and in 1924 he became a member of Council. He was Chairman of the Representative Body from 1928 to 1931. On laying down the office at the Eastbourne Meeting, he made a speech at the Representatives' dinner which was a fine statement of the position of the Association in relation to the public. To summarize it would do injustice to its English, but readers who possess the second volume of the *Journal* for 1931 might well refresh themselves with that speech.

Hawthorne was a purist alike in language, in mode of thought, and in professional conduct, but he was the kindliest of purists, and no one was ever wounded by his satire. He was a great stickler for principle. Over and over again when debate in Council became confused he would with firmness but urbanity reassert the fundamental principle underlying the subject being discussed. This quality of his was sadly missed when he ceased to be a member of Council. Hawthorne was awarded the Gold Medal of the Association at the Annual Meeting at Aberdeen in 1939. The address presented with the medal concluded thus: "The Council of the Association feels sure that it is expressing the wish of the profession as a whole in thus honouring its 'Grand Old Man,' whom it holds in the highest regard and deepest affection."

JOHN D. LONG, M.D.

Dr. John D. Long, who was internationally famous for his work on bubonic plague, died on September 18 in Guayaquil, Ecuador, at the age of 75. He had been in South America for the last twenty-five years.

On his retirement from the public health service in 1938 Dr. Long continued his career as chief travelling representative of the Pan-American Sanitary Bureau. He was loaned repeatedly by the United States Government to assist in the control of bubonic plague in South American countries, where he was a beloved and honoured figure.

A native of Mount Pleasant, Pennsylvania, Dr. Long graduated M.A. at the Washington and Jefferson College in 1897. The college awarded him the honorary degree of D.Sc. in 1929. He took his M.D degree at the University of Pennsylvania, and after a year as an intern at St. Mary's Hospital, Philadelphia, he was in private practice until his appointment to the United States public health service in 1900. During his nearly forty years with the public health service Dr. Long was in charge of the Plague Suppressive Laboratory in San Francisco in 1912–14, and was in Manila from 1901 to 1906 and again from 1914 to 1918. During this second period he was chief quarantine officer and later director of health for Manila and also professor of hygiene at the University of the Philippines. He was also responsible for the reorganization of the Philippine health services. Dr. Long served as technical adviser to the Minister of Hygiene in Santiago, Chile, in 1925–7 and as chief quarantine officer for the Panama Canal Zone in 1927–8. At other times he worked at the Boston and San Francisco Marine Hospitals and at the Hygienic Laboratory, which was the forerunner of the National Institute of Health, the main research centre of the public health service. It was while working with the Pan-American Sanitary Bureau in 1929 that Dr. Long first went to Guayaquil, considered the most plague-ridden port on South America's west coast. By the following summer, through the efforts directed by him, the city was freed from plague. During the next few years cities in Peru, Chile, Argentina, and Brazil were similarly freed from plague by other campaigns stimulated by his leadership.

Dr. Long was perhaps best known as the co-author of the Pan-American Sanitary Code, the Caracas Declaration on the Health of the Child, and the Sanitary Codes of Panama, Chile, and Ecuador. He was a delegate to numerous Pan-American scientific conferences in South America, and was vice-president of the Far Eastern Association of Tropical Medicine from 1925–7.

Dr. Charles Evans Jenkins, who died on September 15 at the age of 59, was one of the few remaining pathologists in Manchester with some private practice. For the last seven months his colleagues had noticed that his health was failing, but, like many a medical man before him, he kept at his work, and on the day before his sudden relapse performed five post-mortem examinations. Dr. Jenkins was born at Dowlais, South Wales,

anxious to obtain privacy as an additional amenity he might be able to do so. Such amenity beds were being increased. It seemed to him to be reasonable that until perfect conditions for everybody could be provided persons who wished privacy in hospital should be able to obtain it. They got the rest of the service free, but paid for the additional amenity of privacy.

Mr. HOWARD said that in these cases the patients were not likely to have the benefit of the doctor of their choice.

Mr. BEVAN said these patients paid only for the amenity. The hospital staffs were available for them. Most people would discover before long that if they paid for a separate specialist of their choice they would have the same one as they would have had in the free ward. He pointed out that the amendment would increase the cost of the National Health Service.

Cost of Free Choice

Mr. LINSTEAD said that taking the hospital service as a whole medical priority determined whether beds were given to a particular patient or not. Only when that principle had been satisfied did the paying patient have any advantage. One of the principles of the Service was the free choice of doctor by the patient. On the whole that principle operated fairly in the general practitioner service, but it did not operate in relation to hospital specialist services except under a very heavy penalty. The only way to get the specialist of the patient's own choice in hospital was by becoming a Section 5 patient and paying the full cost of the bed with the specialist's fee on top of that.

Dr. HADEN GUEST said that before the Health Service came into operation it had been most uncommon for a patient to know anything about the specialist.

Mr. LINSTEAD said that there had been free choice of specialist in that the general practitioner made his recommendation to the patient by saying "you ought to see so and so." In most cases the patient had accepted that advice. Now when the patient went into hospital he had either to accept the specialist who went with the bed or pay the full cost of a specialist chosen by himself or recommended by a general practitioner. The principle of free choice of doctor was violated by the conditions attached to certain Section 5 beds. Also, each of 1,500 or 2,000 individual hospitals to which Section 5 might apply had to arrive at his own weekly figure for Section 5 charges. Even the hospital management committee could not fix a figure for these beds. It was not satisfactory that in a national scheme patients coming into Section 5 beds should have to pay fees varying from £8 to £16 a week according to the overhead costs of the hospital which they entered.

Mr. BAIRD said that if the Opposition complained about high charges for pay-beds the solution was to develop amenity beds faster. In a hospital in the London area last week not a single amenity bed had been available although there were a large number of private pay-beds. Would it not be right to reduce the number of pay-beds and hand them over for use as amenity beds? He pointed out that Wolverhampton Royal Hospital had no private pay-beds.

Lord HINCHINGBROOKE said the amendment only sought to extend the amenity-bed principle and to provide that where specialists were brought in and extra services were given there should still be subtracted from the charge that part of the cost provided by the general hospital service.

Mr. HARRISON said there were complaints from many parts of the country about the growing cost of private beds in the pay-bed block. In his city (Nottingham) the cost would probably soon be £20 a week, which many of the present occupants of the beds could not pay. He suggested that the accommodation in the pay-beds should be transferred for ordinary hospital purposes.

Sir HUGH LUCAS-TOOTH said that in practice the proposal would not increase the cost of the Service. A large number of patients would prefer to make a reasonable payment for their beds and to pay a reasonable fee for the specialist or consultant. But if they were required to pay a specialist fee on top of 20 guineas a week all they could do was to go to a hospital without making any contribution whatever.

Dr. SEGAL said some on the Government side of the House might feel sympathy with the amendment, but when the resources of the Minister were limited they should be concentrated where the need was greatest.

Mr. BEVAN intervened to say he had asked for an investigation to be made of the number of free patients in pay-bed blocks to check to what extent free patients were not admitted on entirely medical grounds to these blocks. His information was that at least 40% of the pay-bed blocks were occupied by free patients. That was a tribute to the way in which the administration was carrying out the terms of the Act. Mr. Bevan said that some time ago he had sent out an instruction that the patient was to be told by the general practitioner or the specialist whether he was to be treated under the National Health Service or as a fee-paying patient. It was the obligation of the doctor to inform or to ask the patient whether he or she wished to be treated as a free patient or as a fee-paying patient. He would be grateful for examples where this procedure was not followed. It was not proper for a medical practitioner or specialist to promise that a person would get into hospital sooner by becoming a private patient. It was the duty of hospital authorities to admit patients on medical grounds, and the figures he had given showed that in most cases this had been done.

Mr. RICHARD LAW said that if existing tendencies continued and if prices continued to rise the private patient would be driven out of the National Health Service hospitals. All that was asked under the amendment was that the private patient should be treated in exactly the same way as the public patient and have exactly the same privileges.

Dr. MORGAN said there should be no further extension of the pay-bed system by which certain patients could get additional benefits. The subject had been fought out in the medical profession, and the professional men had decided in favour of the Act as it stood.

The Committee then divided, and the amendment was rejected by 256 to 139.

Private Patients at Health Centres

Mr. ANEURIN BEVAN then moved an amendment that: "At the end of paragraph (*a*) of subsection (1) of Section 21 (which requires facilities at health centres to be available for the provision of general medical services), there shall be inserted the words 'and, on such terms and conditions as may be determined by the Minister, for the provision by medical practitioners of such other personal medical services (if any) as may be so determined in the case of a particular health centre.'"

He said the purpose of this amendment was to enable general practitioners to treat private patients in health centres. At one time he had set his face against that proposal, but the number of persons outside the scheme was now so small that no danger could arise to the structure of the Service by allowing general practitioners to take their private patients into the health centres. It would be unreasonable when a health centre was available to expect a general practitioner to maintain a private surgery at which to treat his private patients. When health centres were available the Ministry would make it clear by regulation that there should not be two doors—one for the private patient and one for the public patient. The private patient must take his proper place with the general public in seeking the services of his doctor. The Ministry would also rule that a doctor should have a substantial number of patients in the public scheme before he could avail himself of private facilities at a health centre. A subcommittee of the Central Health Services Council had recommended that it should be possible for a general practitioner to treat private patients in a health centre.

Lord HINCHINGBROOKE said Mr. Bevan was constructing castles in the air. There were no health centres and the Minister's speech was irrelevant. There might be just one experimental centre which had been started before Mr. Bevan had anything to do with the health service. In the last four years during which he had full opportunity to build them he had not done so.

Answering Mr. Orr-Ewing Mr. BEVAN explained that he would determine which doctors were entitled to treat private patients in a health centre under the words of the amendment "on such terms and conditions as might be determined by the

Minister." The proportion of private patients and listed patients would be discussed when the regulations were laid before the House.

The amendment was then agreed to.

Mr. BEVAN then moved a further amendment as follows:

"In Section 46 (which provides for the use of health centres by practitioners) after the words "general medical services" there shall be inserted the words "or other personal medical services or," after the words "subject to regulations" there shall be inserted the words "and to any determination by the Minister under Section 21 of this Act," and after the words "the Executive Council may" there shall be inserted the words "subject to any such determination as aforesaid."

Mr. Bevan said the purpose of these words was to enable the Executive Council when directed by the Minister to make differential charges on general practitioners varying with the amount of use they would make of the health centre for their private patients. It was clear that the general practitioner would have to pay a charge because he would be relieved of the necessity of maintaining his surgery. This was a matter for future discussion with the representatives of the medical profession. He did not think any general practitioner would quarrel with this. The amendment was welcomed by Mr. Elliot and agreed to.

Certificates

Mr. BEVAN then moved a further amendment as follows: "In paragraph (*d*) of subsection (2) of Section 33 (which provides for the issue by medical practitioners providing general medical services of certificates reasonably required under or for the purposes of any enactment) after the word 'of' there shall be inserted the words 'such certificates as may be prescribed being.'" He said that before the Health Service Act came into operation the Secretary of State for Scotland and himself had appointed a committee to try to reduce the number of certificates which doctors had to provide. That committee, known as the Safford Committee, had issued an interim report.

Mr. LINSTEAD said the House welcomed anything that would cut down paper work on the part of medical practitioners, but he suggested that the Minister might be curtailing the freedom of patients to get free of charge some certificates required for statutory purposes.

Mr. BEVAN said that as the free certificates required would be listed in the regulations the matter could be raised when these were debated. The Safford Committee had stated that a list of free certificates should be provided and that the words of the original statute, which were very extensive, should not be applied.

Dr. MORGAN asked whether the report of the Safford Committee would soon be published.

Mr. BEVAN said he did not like to hurry the committee in its work, because it was necessary that the report should receive general acceptance. Parliament would be substantially guided but not bound by what the committee recommended. He did not think it would be necessary to have the list of prescribed certificates ready at the exact moment when the present Bill came into operation.

The House agreed to the amendment. Mr. JOHN WHEATLEY then moved an amendment applying to Scotland the principle of the earlier amendments dealing with the right of doctors to use the health centres for private patients. The House agreed to this amendment, and the schedule as amended was ordered to stand part of the Bill.

REPORT STAGE

The Report stage followed immediately. A new clause (Prohibition of full-time salaried dental practitioner service) was brought up, read a second time, and added to the Bill. The purpose of the clause was to carry out in the case of dentists the same undertakings that had been advanced in the case of general practitioners.

Mr. WHEATLEY moved another new clause under which a child under 16 could be admitted as a voluntary patient in a mental hospital on the application of the parent or guardian. Developments in this branch of medicine were such that it was desirable that children should be able to get full advantage of them as voluntary patients.

The clause was read a second time and added to the Bill.

Dental Ethics

Mr. BAIRD moved a new clause which read: "No dental practitioner who is on the list of a local executive committee and is accepting patients under the National Health Service shall be entitled to accept remuneration from private patients." Mr. Baird, himself a practising dentist, said a number of his constituents suffered because of the unethical practices of a number of dentists in his division (East Wolverhampton). When the National Health Service Act had been discussed he had fought for the liberty of the dental and medical professions to treat both private and public patients, but with reluctance he now moved to withdraw that right from the dental profession. The racket now going on in the dental profession in regard to public patients must be stopped. A patient who was in pain and went to a dentist to have a tooth removed was told that the dentist was fully booked up for six weeks, but if the patient offered to pay the dentist would take the case right away or within an hour. Under the National Health Service Act payments were offered to dentists by means of an itemized scale of fees for every operation. The operation of filling was better paid than that for fitting dentures. A number of dentists were accepting patients who required fillings but refusing those who required dentures. A third abuse was that of "talking down" the National Health Service Act. The dentist said to the patient, "If you come to me under the Act I can only give you second-rate treatment. If you want a good job, come to me privately." Mr. Baird said he had particulars of such cases from all over the country, but there was great difficulty in proving them. The discussion usually occurred between the patient and the receptionist. He estimated that at least 75% of dentists were turning away patients in pain unless they were prepared to pay.

In his opinion the real solution was large-scale health centres with a fully salaried dental service. A temporary solution would be a simplification of the regulations which allowed a patient to make representations to the local executive council. The only other solution was for the profession itself to discipline its members. He had received from one of the dental organizations a letter placing on record its disapproval of the amendment he had sponsored. This letter declared that if the proposed amendment was pursued the association would resist it to the utmost. Even if Mr. Bevan could not accept the amendment Mr. Baird appealed to him to let it be known that the House condemned those dentists who turned away patients in pain unless they were prepared to pay.

Mr. SPARKS seconded the proposed new clause and said the Minister had had a large number of cases brought to his attention by Members.

Sir HUGH LUCAS-TOOTH said the Opposition fundamentally opposed the new clause. To add it to the Bill would be a gross breach of faith with the dentists. The over-riding difficulty of the dental service was that there was more work to do than the dentists could accomplish. A lot of respectable professional men said to themselves that they were prepared to work eight or ten hours a day in the public service and would reserve two or three hours for private practice. There was nothing unethical in that.

Dr. GUEST asked whether it was ethical for dentists to devote one day a week to National Health Service patients and keep the rest of the week for private patients.

Mr. PAGET said the whole point was that the doctors had played the game and the dentists had not.

Sir HUGH LUCAS-TOOTH said that even now the fees paid to dentists for public patients were fully as high as those which were paid for private patients.

Mr. BAIRD said that every penny of the dentist's income received from the State was declared to the income-tax authorities, but there was no way of checking so far as his private patients were concerned. After due consideration he made the charge that in a large number of cases a considerable amount of the dentist's private income was not declared because it was

so difficult for the income-tax authorities to prove what was his real income.

Mr. BEVAN said he had never seen such a complete exposure of general ethics as that made this afternoon from the other side of the House. Sir Hugh Lucas-Tooth had suggested that if a patient went to a dentist's surgery in pain it would be ethical on the part of the dentist to prefer to treat a private patient who would pay more. Members of the Opposition put professional solidarity over the public interest. The dental profession had been guilty of worse conduct than any other profession in the Health Service. It was the duty of the Opposition to deprecate unprofessional conduct and not to try to justify commercial discrimination—the ethics of the jungle—against people in pain. Mr. Bevan said he was satisfied that misconduct was decreasing and that the behaviour of the dentists, generally speaking, was improving. Therefore it was better to allow the disciplinary machinery which had been established under the scheme to operate against the person who was misbehaving. He hoped that before long the good would drive out the bad. If a dentist was overworked, how was it possible for him to do the work privately but not publicly? The trouble at the beginning of the scheme was that there was exploitation of scarcity value by the dental profession as a whole. The largest organization of dentists did not advise its members to join the National Health Service. They had come in as individuals. The National Health Service had been introduced to enable ordinary citizens to have access to medical skill without being blackmailed in doing so. That was the whole point of it. The Ministry had tightened up the situation so that a dentist could not say now that he would extract teeth under the National Health Service and provide dentures privately. He was sure that first-class people in the dental profession would be pained by the belief that the general public did not hold the dental profession in esteem, and he hoped the House could look forward to a general improvement in the Service.

After further discussion Mr. Baird withdrew his proposed clause.

Overseas Visitors

Mr. ELLIOT moved a new clause providing for regulations to prescribe charges for services rendered under the Act to persons not normally resident in the United Kingdom. Mr. Elliot said that it would be easy for visitors to pay a charge. The Minister had said at a Press conference that he had arranged for immigration officers to turn back aliens who were coming to this country to secure the benefits of the Health Service. To place this duty on these officers was asking them to do a thing which they were not competent to do. Surely the proper person to examine a visitor was one with medical skill. The proposed amendment suggested a solution which would meet the difficulty in a practical way. The Minister would allow a person who was seeking attention to pay a sum according to circumstances which the Minister would determine.

Mr. BING said there were about 635,000 visitors to this country in the course of the year who on the average stayed less than a month. They were equivalent to a population of about 50,000 extra people requiring health services. Supposing they made the same demands as the people in this country, the cost would be between £200,000 and £250,000. The machinery required to meet the amendment would involve an administrative cost as great as that.

Mr. BEVAN said it had been sickening during the last fifteen months to witness members of the Opposition going round the country spending most of their time on the platform poking fun at the Health Service and undermining it. The assumption that there was something wrong in treating a stranger who was visiting this country and fell sick was one of the curses of modern nationalism. It was not part of the ethics of mediaeval society. The present attitude was a by-product of the existence of the Conservative Party.

The health services of the whole world were being stimulated by what was happening in Britain, and a constant stream of visitors came from all parts of the world to find out what we were doing. Most of them returned hoping that what we were doing would succeed so that they could imitate it in their own countries. If a person left another country deliberately for the purpose of going to Roehampton to get an expensive artificial limb he would consider that to be an abuse, but if a person came to this country and fell sick it was proper that he should be treated. Some British institutions had always done so. The great Scottish hospitals treated visitors freely, and until recently many of the great London hospitals had followed that tradition. He was not prepared to establish administrative arrangements which would harass the whole population merely to deal with a handful of people who were visiting this country. Unless they were careful they would find themselves denying the health service to many British subjects not normally resident in this country. However, he proposed to take power in the House of Lords to frame regulations to prevent abuse of the health service in this country by overseas visitors where it might be practicable so to do. The House must look at the regulations when they were issued to see how far they went towards meeting the difficulties of certain cases. He must not be understood to agree that it was desirable that any person in this country not being a resident who fell sick ought to pay a charge for the use of all or part of the health service.

Mr. Elliot recommended the Opposition to accept Mr. Bevan's promise of an amendment and to see what the position was when that amendment finally returned from the House of Lords. He then withdrew the proposed new clause.

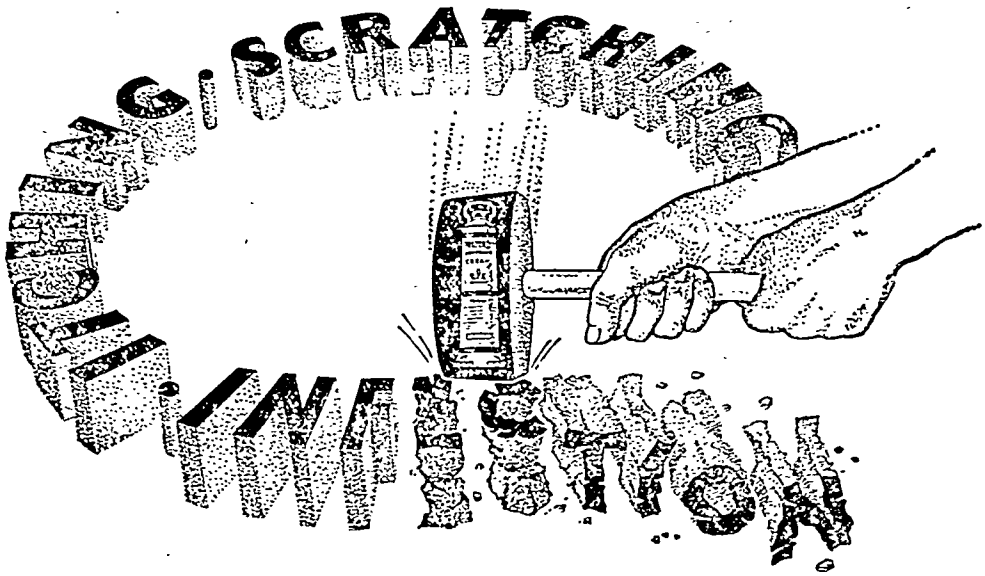
Too Heavy a Hammer

A new clause was brought forward by Mr. MARLOWE. It ran:

> "Regulations may authorize the Minister, if he thinks fit, to publish particulars of any disciplinary action taken by him in respect of any breach of any regulation under the Act of 1946 or the Act of 1947, including the name and address of any person in respect of whom such action is taken and the name of any executive council recommending such action."

Mr. Marlowe said that recently a practitioner had been dealt with by an executive council and fined the maximum amount of £100 for what was called "infamous or scandalous conduct" under the Act and for deceiving innocent patients. It had not been found practicable to publish the name of this offender in the Press lest the executive council found itself open to an action for libel. Mr. Marlowe said the amendment was designed so that if the name of the offender was published under the direction of the Minister the executive council would be protected against libel action and full publicity would be given. Mr. ELLIOT seconded the proposed clause.

Mr. BEVAN said there was a difficulty at the moment, but the new clause was too heavy a hammer for this nut. In the central tribunal, which was a judicial body, decisions were published with the names and penalties. In the case of the local committees procedure was not so formal and judicial, and it did not seem to him that the name of the offender and his punishment should be published. It could not be said in such instances that the full procedure of the judiciary had given protection to the person involved. As a general rule the name was known to the local population and therefore the utmost deterrence was achieved. To publish the name in the local press might cause hurt to individuals who might have been guilty of thoughtlessness or something of the sort. The existing machinery worked well, and he was content with giving full publicity to the decisions only of the central tribunal.



The proposed new clause was negatived.

On Clause 20 Mr. BEVAN moved and the House accepted an amendment providing that medical officers of regional hospital boards or teaching hospitals should not be paid for examinations carried out or certificates given in respect of mental patients when these things were carried out in the ordinary course of their duties.

On Clause 23 drafting amendments were made on the motion of Mr. BEVAN, and the House agreed to them.

General Practitioners' Access to Hospitals

On the Schedule of minor amendments Colonel STODDART-SCOTT moved an amendment. He said that at present anybody

POLYCREST

ANTIPRURITIC CREAM

A Causal and Symptomatic Therapy

THE "VICIOUS CIRCLE" OF PRURITUS

In the past in the treatment of pruritic conditions counter-irritants were employed which merely superimposed pain on itching.

To-day it is realized that antipruritic therapy can only be effective if it is not only curative but also breaks the 'vicious circle' of itching — scratching — infection — more itching — and so on.

A CAUSAL AND SYMPTOMATIC THERAPY

This modern approach to the problem is embodied in Polycrest Antipruritic Cream, which combines the high bactericidal and fungicidal properties of Phenylmercuric Nitrate with the prompt and prolonged surface anaesthetic action of Amethocaine and Benzocaine, thereby affording simultaneous causal and symptomatic therapy.

INDICATIONS

Pruritus Ani, Haemorrhoids, Anal Eczema, Diabetic Pruritus and other pruritic conditions of diverse origins, including Epidermophytosis and other Tinea infections.

FORMULA

Phenylmercuric Nitrate	..	0.25%
Amethocaine	.. ..	0.50%
Benzocaine	.. ..	5.00%
Cream Base	.. ..	*q.s.*

C.P.L

CLINICAL PRODUCTS LTD. RICHMOND, SURREY, ENGLAND.

For Control in Parkinsonian States

PARPANIT

Trade Mark Brand

1-phenyl-cyclopentane-1-carboxylic acid diethylaminoethylester hydrochloride

PARPANIT is a new substance for the treatment of conditions characterised by muscular rigidity and tremor, particularly Postencephalitic Parkinsonism and Paralysis agitans; it has been the subject of many clinical trials, including that reported in *The Lancet*, 1948, 2, 724. The action of Parpanit is not limited to the relief of symptoms of disorders of the extrapyramidal system and a trial is justified in all affections accompanied by an increase of muscle tone.

Geigy

Why 'Ribena' in Peptic Ulcer?

Ribena is being increasingly prescribed in the treatment of Peptic Ulcer because controlled clinical tests have clearly indicated that *natural* vitamin C, in the form of blackcurrant syrup, accelerated disappearance of symptoms and X-ray evidence of ulcer. Detailed information on this work will be gladly sent to physicians.

Ribena is the pure undiluted juice of fresh ripe blackcurrants with sugar, in the form of a delicious syrup. Being freed from all cellular structure of the fruit, it cannot upset the most delicate stomach. It is particularly rich in natural vitamin C (not less than 20 mgm. per fluid ounce) and associated factors.

Eire.—Inquiries should be addressed to Proprietaries (Eire) Ltd., 17/22, Parkgate Street, Dublin.

entering a Section 5 bed of a hospital must be cared for either by one of the honorary staff or one of the resident staff of the hospital. It was impossible for a general practitioner who had been treating the patient or even for an outside specialist to continue looking after that patient should he obtain admission to one of these pay-beds. General practitioners should not be prevented from treating their own cases in hospital. The fact that they could not do so threw an extra burden on the staffs of the hospitals. Hospitals had borne the greatest burden of the National Health Service. *This would be relieved to some extent* by permitting general practitioners who were not members of hospital staffs to care for those of their patients who occupied pay-beds. *In small general hospitals a maternity case, for* example, must be looked after in a pay-bed either by the general surgeon or physician or the resident doctor, who in many cases knew less about maternity than the *general practitioner.* This amendment would enable these patients to be cared for in hospital by their own medical practitioners. It would retain what Mr. Bevan always said he wished to retain, free choice of doctor by the patient.

Sir HUGH LUCAS-TOOTH seconded the amendment, and said there was a feeling in the medical profession that it was being divorced from access to hospitals. Doctors should not be given that impression. If the Government intended to kill private practice that intention should be stated.

Sir HENRY MORRIS-JONES recalled that when the main Act had been in committee Mr. Bevan had held that there should be a strong line of demarcation between the general practitioner and the specialist. *Since then, to his credit,* he had modified his views. A recent circular (*Supplement*, October 15, p. 168) distributed by the Ministry of Health to hospitals had urged that more facilities should be given for general practitioners, particularly in cottage hospitals and smaller provincial hospitals. It would be a pity if facilities were denied for maintaining what Mr. Bevan had assured the medical practitioners to be his intention, that the right of private practice would still be available and that they should have an opportunity of carrying on in that respect within the framework of the Act.

Mr. MESSER said it was generally accepted that if the Service was to succeed the country must have not merely an efficient hospital service but an efficient general practitioner service too. He was not sure that specialization to the extent to which it appeared to be developed in the profession was a good thing. It might be good if specialization had a very good general background. For that reason a high standard of domiciliary service was of immense importance. No barrier should be placed in the way of improving the standard of the general practitioner. If that meant access to hospital beds, it should be organized in a way which would provide the general practitioner with that contact without adversely affecting other aspects of the Service. But, as he read the amendment, it would enable a patient to be admitted to hospital by *jumping the queue.* Once a general practitioner with access to a hospital could get his patient admitted more speedily than another general practitioner, another patient would be disadvantaged. If there was value in a general practitioner having access to hospitals, all general practitioners should have the same opportunity. That was not the case. In Central London no cottage hospital or general practitioner hospital existed.

General Practitioners and Specialists

Mr. BEVAN agreed with Mr. Messer that there had been a tendency to dig too wide a gulf between the general practitioner and the specialist. If that gulf was to be narrowed it was not necessary to do so by legislation. It could be done by agreement between the members of the medical profession. It would be wrong to admit the right of a general practitioner with private patients to have access to hospitals where his colleagues were denied that right. General access of general practitioners to hospitals was an entirely different matter and one for discussion *administratively, not by statute.* What was really envisaged in the amendment was that a specialist not in the public service should be able to treat his private patient in a hospital. *That he considered* to be wholly wrong. If a specialist did not wish to be in the Health Service and therefore had not attached himself to a hospital, Mr. Bevan *did not think that such a man* was entitled to use the Health Service. He would not be much good for long if he were not attached to a hospital. A specialist *ought to live in the climate of the hospital as much* as possible to do his work properly. Mr. Bevan said he was unable to accept the amendment. If the general practitioner was to follow *his patient into the hospital where that patient had been* entrusted to the specialist, there might be a considerable quarrel over the claims of both to have charge of the treatment, and between the quarrels of two members of the profession the patient might succumb.

Mr. QUINTIN HOGG said a public hospital under the scheme *was neither a weapon for the Minister to coerce specialists or* general practitioners into the scheme nor a privilege for the use of specialists or practitioners. It was a convenience for the public and, in particular, a service for the patient. The House was talking about people who were suffering and whether these people were better treated inside a general hospital or should have to stay, as an unprivileged class, in their own homes. If the treatment of a person was better effected in a public hospital that person should be allowed to go there. If Mr. Bevin denied that person the right, within reason, to select his own medical attendant or adviser, he was breaking one of the fundamental agreements in the scheme, which had hitherto not been in dispute.

Mr. BEVAN *asked whether Mr. Hogg suggested that a patient* should have the right in any hospital to be treated by the general practitioner of his choice, whether attached to that hospital or not.

Mr. HOGG said the limitation of the right of the private patient in a hospital to be treated by the medical attendant of his choice should be defined by purely medical considerations and not by political considerations. He included in political considerations Mr. Bevan's argument that one did not wish to encourage specialists who did not belong to hospitals. That was trying to discipline the medical profession.

Mr. BEVAN contended that if a statutory right were given to a general practitioner to enter a hospital and treat a patient there *would immediately* be administrative troubles of the greatest possible kind. What was desirable was that eventually there should be a closer identification between general practitioners and the work which went on in hospitals.

On a division the amendment was rejected by 253 to 103.

Grading of Specialists

Sir HUGH LUCAS-TOOTH moved to insert in the Schedule the words:

"Subsection (2) of Section 14 (which provides for conditions of service and appointment of medical or dental officers employed on the staff of hospitals providing hospital and specialist services) shall have effect as if the following sub-paragraphs were added:

'*(e)* for the establishment of a Central Professional Committee and for the hearing by such committees of appeals from officers engaged in the provision of hospital and specialist services who are dissatisfied with any decision under this subsection of any regional hospital board or board of governors relating to their status;

'*(f)* for the determination by the Minister after consideration of the recommendations of the Central Professional Committee of any such appeal as may be made under the provisions of the last foregoing sub-paragraph.'"

Sir Hugh recalled that before the Act came into operation specialists fell roughly into three groups: the house officers, the registrars, and the fully qualified specialists. About the time of the introduction of the Act the Spens Committee recommended that the specialists should be divided into two main groups, the junior of which was to be the registrar group, with a smaller group of fully qualified specialists. The Minister had introduced a third grading, the senior hospital medical officer. *Sir Hugh did not contest the division of specialists into three* grades.

He was concerned, however, with the grading of individuals. Under the Minister's regulations, specialists had to be placed in appropriate grades by the regional hospital board, or the board of governors in the case of a teaching hospital. That was done through the advice of a reviewing committee. If the specialist was dissatisfied with the grade in which he was placed

his only appeal was to the board whose reviewing committee had in fact appointed him. Whereas in the old days it might not have been a matter of vital importance what the specialist was called, to-day his whole career must depend on the grade in which he was placed. Sir Hugh did not say that the grading had been badly carried out or that there were a great number of mistakes. He contended that a great number of those graded felt they had not been properly judged in this matter. One reason for this sense of injustice was that the grading had been done by the local board of the hospital to which the specialist was attached. The purpose of the amendment was to give a right of appeal to those who had a grievance. It proposed that the Minister should constitute a central committee to deal with the question of status.

Lord HINCHINGBROOKE seconded the amendment. He said the Minister must be conscious of a great tide of complaints from consultants and specialists under the National Health Service relating to harsh treatment at the hands of regional hospital boards in having their status downgraded as the result of the Minister having varied the terms of the Spens Report. He had had a large number of cases brought to his attention from the provinces. In the first place the complaint was against the original assessment being made by men who had been described to him as "superior persons in the medical fraternity who gravitated to the metropolis, men who are cut off by many years now from the knowledge of what kind of work is being done in the provinces." One communication had defined the selecting team of assessors on the Central Hospital Board as "men who suffer from the belief that London in general and Harley Street in particular harbour all but the incompetent nonentities in the specialist branches of medicine." Complaints were not uniform from all parts of the country. That showed that the treatment of the subject by the various regional hospital boards varied considerably. Some had initially graded too high and intended to downgrade in the interest of economy. Other regional hospital boards—he instanced the South-Western Metropolitan Regional Hospital Board—seemed to have downgraded almost everyone, but allowed certain cases on appeal. It was unsatisfactory that the boards should differ so substantially in their methods.

The Opposition contended that the appeal should be instituted by the man who was downgraded and should lie to a different body altogether, but not to the Minister. Lord Hinchingbrooke cited the appeals open to Army officers who felt aggrieved at their standing. He said Mr. Bevan had rushed into a national medical service on military lines, but had not devised the network of safeguards which the Services had been obliged to develop. Mr. Bevan would find a useful precedent in the Services. New machinery was imperative if the National Health Service was not to degenerate through disillusion and cynicism which was growing in the profession, especially among consultants and specialists who had been downgraded. Lord Hinchingbrooke added that the Opposition was not wedded to the actual form of the amendments. If Mr. Bevan would indicate the appropriate machinery that would be introduced into the Bill while it was before the House of Lords, Conservatives would be satisfied.

Mr. BEVAN said the amendment was maladroit. Section 14 of the Act dealt with the appointment of persons who had already been qualified. It had nothing to do with their status. The amendment directed itself to the grading which had recently taken place of persons in the specialist class. People had assumed that because the regional hospital boards made appointments on the staffs of specialists they actually made the classification of specialists. That they did not do. There was no academic qualification in the medical profession which corresponded to a hierarchical arrangement. He did not agree with the hierarchical conception in which the general practitioner was placed at the bottom. The first-class general practitioner was the cream of his profession. To say that any person had been downgraded or upgraded in relation to whether he was further from or nearer to the status of a general practitioner would immediately poison the atmosphere. Since they had to have different scales of remuneration they had to have a classification. The task of ensuring this had been entrusted, on the advice of the medical profession, to a purely professional body. That was one of the defects in the amendment which suggested that after the doctors had been classified by their fellows they should appeal to the Minister. It proposed that a person should be examined first by the local medical professional committee, and, having a grievance against the committee, he should appeal to the Central Professional Committee and then appeal to the Ministry.

Apple of Discord

Mr. BEVAN said his legal advisers told him there could be no other interpretation of the words in the amendment. The Ministry would be the last court of appeal for determination of the professional status of a member of the medical profession. He could not dream of doing that. The medical profession would be horrified if it thought that a lay Minister should be allowed to classify specialists in the profession. They were not dealing with jurisprudence, but with the proper classification of a person in the practice of his profession in the absence of objective data. To do that they had called into existence a local professional committee containing all the specialties about which classification was to be made. As people were being classified on their craftsmanship, the more immediate and precise the knowledge the more just the conclusion was likely to be. Therefore a local committee did the classification. This was done for the first time in medical history and was bound to be empirical. Therefore the Government had decided that a further review should take place—a review, not an appeal. If a person wished to have his case reviewed it could be referred to two persons outside the region who would bring fresh minds to bear. That was in process of taking place and it would be a disaster if Parliament churned it all up again. Members might satisfy the small number of persons who wished to appeal, but would dissatisfy a large number of those who had been established. All those who were fitting themselves into their positions would feel insecure. The whole of the findings of the local committee would be exposed to doubt. Further, the central committee would consist of the same type of people as the local committee, but with less knowledge about the individuals concerned. It was inevitable that a lot of individuals should have a feeling about the sieve through which they had been passed, but a grievance was not necessarily entitlement to appeal. To throw this apple of discord into the arena would be resented by the profession.

Mr. HOGG remarked that Mr. Bevan had talked nonsense for a great part of his speech. He was grateful to Mr. Bevan for having pointed out a drafting defect in the amendment, which had been put in the wrong place, since local hospital boards were concerned with appointments but not with classification. The important practical question was how to exclude from the circle of specialists those with no qualification to call themselves such. The Minister was right to have entrusted the question of classification to a local body, but what the Minister had failed to understand was that it was vital to have a single standard throughout the country, which could not be obtained by the operations of a local man working alone.

Mr. BEVAN intervened to say that the absence of an objective test made uniformity impossible. The professional status of the individual in the conduct of his work constituted his entitlement.

Mr. HOGG agreed that responsibility must lie, in the first place, with the local committee. He thought the conclusion which followed was that a central professional body should supervise the work of the local committees. He did not think it impossible to deal with these matters on appeal. The Central Professional Committee which was suggested would be a co-ordinating body of practical men deciding cases on practical principles and evolving a code of practice which would give the desired uniformity. Mr. Hogg accepted Mr. Bevan's assurance that the Minister's new proposal that there should be a review, with two added persons from outside, was acceptable to those concerned. But the Minister had not persuaded him that it was not desirable for a purely professional body to overlook the work of the local committees.

Dr. MORGAN said he had pleaded for years for a recognized scheme by which specialists and the different grades in the

profession could be recognized. The public was disinterested. People did not care a hoot who called himself a specialist. The Minister had that night been most conciliatory on this most difficult of all problems. He did not see why the Minister should be scared at taking the advice of a Central Professional Committee. There was in the profession and among the most competent specialists a great deal of dissatisfaction at the way things had gone so far. Mr. Messer had remarked that there had previously been no grading. Dr. Morgan said that many a man who failed to get his F.R.C.S. did not fail altogether from lack of learning. When he himself failed in the primary F.R.C.S. examination one of the examiners had pulled him aside and said, "You did not fail because you did not know the subject, but because you are too keen on socialist policy." That might be changed now, because Labour had grown respectable.

Mr. Walter Elliot said the point under discussion was important and no political profit could be made from it by either side. Everyone had pointed out that there was no medical hierarchy, but one was being brought into being. The problem, therefore, was a new one. It would pass, once the hierarchy had been established. To classify persons whose qualifications were craftsmanship, competence, and behaviour was difficult. The responsibility of a layman was admitted in the case of the Home Secretary, who was a final court of appeal, or in that of the Secretary of State for Scotland, who made the final appointment to some of the greatest university chairs in Scotland. From all the arguments brought forward that night he thought that appeals to some body which was not the local body would be of great advantage. Nobody denied that a sense of grievance existed. He did not think Mr. Bevan had dealt fully with the matter.

The amendment was rejected by 241 to 97. Drafting amendments were made to give the local optical committee the same statutory position as the local medical, pharmaceutical, and dental committees.

The Bill was then read a third time without further debate.

Limiting N.H.S. Lists

Sir Ernest Graham-Little inquired on October 18 under what sanctions executive councils subjected medical practitioners in the National Health Service to a heavy tax upon their payments from the Service if they refused to undertake a large panel.

Mr. Bevan replied that the regulations governing the remuneration of general practitioners provided for the adjustment of remuneration in the case of a practitioner who was exempted from the liability of having persons assigned to him and was relieved of obligations for emergency night calls in respect of persons not on his list. There was nothing to stop a practitioner limiting his list without applying for these exemptions.

Appeal to the Minister

Sir Ernest Graham-Little also invited the Minister of Health to review his refusal to modify decisions taken by executive councils, since the composition of these bodies was predominantly lay.

Mr. Bevan answered that any person aggrieved by the decision of an executive council on a case investigated by a Service Committee had a right of appeal to him under Regulation 7 of the National Health Service (Service Committees and Tribunal) Regulations, 1948 (Statutory Instruments, 1948, No. 507). The members of an executive council, excluding the chairman, were half professional and half lay.

Hearings Before Medical Services Committee

On October 20 Sir Ernest Graham-Little asked the Minister of Health why he refused the assistance of the Medical Defence Union to doctors who were accused before the Medical Services Committee of professional negligence.

Mr. Bevan replied that the regulations permitted a party to an investigation by any service committee of an executive council to be assisted in the presentation of his case by some other person, provided that no person should be entitled, in the capacity of counsel, solicitor, or other paid advocate, to conduct the case for any party by addressing the committee or examining witnesses. Mr. Bevan saw no reason to alter these arrangements.

Contraceptives in Slot Machines

Answering Sir Henry Morris-Jones on October 20, Mr. Ede announced he had given instructions for a model by-law to be drafted prohibiting the sale of contraceptives by means of automatic machines. This model by-law would be circulated to all county and borough councils for their consideration, and if adopted would be subject to confirmation by the Home Secretary. He had given most careful consideration to the question, and had come to the conclusion that the social mischiefs involved were so serious as to require immediate action.

Sir Henry Morris-Jones said the whole nation would be relieved by the attitude which the Home Secretary had now adopted. He asked how soon the procedure would be completed, as the exhibition of these machines was extending rapidly all over the United Kingdom.

Mr. Ede said he would see that the procedure was carried through with the utmost expedition. The reception given by the House to the question would show the activity of the public conscience in the matter.

Mr. Eden asked why the Home Secretary preferred procedure by a model by-law and not by legislation.

Mr. Ede said he held that the Government should make arrangement for enforcement by local means and thereby secure the active approval of the local authority to ensure the law would be enforced. Answering another inquiry, Mr. Ede said that there were no special machines for this purpose.

Children's Hospitals.—Replying, on October 18, to Sir Ernest Graham-Little, Mr. Bevan reported that no children's hospital had been closed since the coming into operation of the National Health Service, although two were no longer used exclusively for children. The total number of children's beds available had increased by 1,278. The number of children's beds available in general hospitals was 16,449 and in special hospitals 23,302.

Sickness Benefit Claims.—Mr. James Griffiths, answering Sir Waldron Smithers on October 18, said the steps taken to supervise sickness benefits claims under the National Insurance Acts were broadly the same as those followed by the approved societies under the old National Health Insurance scheme. They included careful scrutiny of claims, sick visiting in selected cases, and the use of the Regional Medical Service of the Health Departments to obtain second medical opinions in cases of doubt.

Priority Milk.—Asked on October 19 what percentage of the milk supply was going to persons with a doctor's priority certificate as compared with a year ago, Mr. Strachey said that last winter the percentage was 6·1. The Ministry of Food had not collected statistics for this winter yet. The minimum milk supply to hospitals was five pints per head per week. A supplier can sell to hospitals extra quantities beyond the minimum if he had any surplus after meeting the needs of domestic consumers.

Spectacles.—Mr. Bevan states that about 3,000,000 pairs of spectacles were on order on September 1, 1949. He reports delays in supply of anything up to six months or so, although by no means all cases take as long as that. Better supplies are improving the position steadily. In the years ended September 1, 1948, and September 1, 1949, 4,500,000 and 9,900,000 spectacles were ordered.

Food-poisoning Outbreaks.—Mr. John Morrison asked on October 20 what was the total number of reported cases of food-poisoning in each of the years 1945 to 1948 as compared with 1935 to 1938. Mr. Bevan said he had no information about the number of persons affected in each of these years. The following figures relate to the number of outbreaks reported. In the years from 1935 to 1938: 137, 82, 94, and 156; and in 1945 to 1948: 422, 598, 765, and 964 respectively.

The Ministry of Health has informed hospitals that posts for pharmacists in the basic grade (assistant pharmacists) may be advertised with the salary scale £425 × £25 – £525. A reduction of £25 will be made for every year below the age of 23. The Pharmaceutical Whitley Council is considering the remuneration of existing staff, and when agreement has been reached the terms will be made retrospective to July 5, 1949.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 8. [No. 40

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications in the week ended October 15 were: poliomyelitis 418 (340), polio-encephalitis 45 (34). Figures for the previous week are shown in parentheses. There has, therefore, been a substantial rise, and it is clear that the curve is following a different trend from that of 1947.

Multiple cases were reported from the following counties: London 68 (53), Bedford 7 (5), Berkshire 4 (6), Buckingham 2 (2), Chester 7 (5), Cornwall 6 (2), Cumberland 7 (1), Derby 2 (1), Devon 2 (3), Dorset 10 (7), Durham 4 (2), Essex 39 (31), Gloucester 21 (23), Hereford 3 (0), Hertford 11 (4), Huntingdon 5 (0), Kent 33 (22), Lancaster 32 (24), Leicester 10 (4), Lincs. Holland 9 (0), Middlesex 18 (30), Norfolk 8 (4), Northampton 4 (4), Northumberland 3 (0), Nottingham 11 (8), Somerset 9 (6), Southampton 10 (4), Stafford 3 (1), East Suffolk 3 (4), Surrey 14 (8), East Sussex 4 (2), West Sussex 2 (1), Warwick 16 (19), Wiltshire 8 (4), East Yorks 3 (2), North Yorks 3 (3), West York 48 (50), Glamorgan 4 (7).

In the United States 33,144 cases of poliomyelitis had been reported this year up to October 1. The total for 1948 was 27,908. For the first time since July 30 there are now fewer than 2,000 notifications a week.

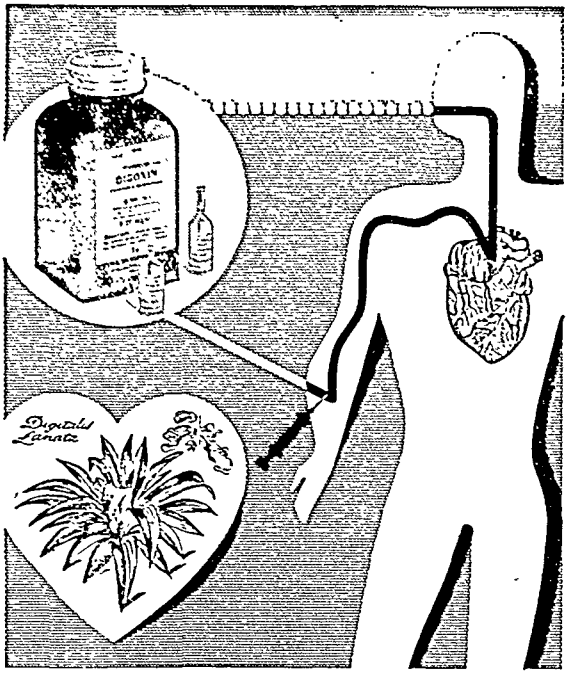
Discussion of Table

In *England and Wales* there were increases in the notifications of scarlet fever 319, measles 146, and dysentery 127, with a decrease of 48 in the incidence of whooping-cough. Poliomyelitis and polio-encephalitis with increases of 9 and 8, respectively, reached the highest level of the present outbreak.

The rise in the incidence of scarlet fever was chiefly in the northern section of the country; the largest rise was in Yorkshire West Riding 59. The increased incidence of measles was due to a general increase in the northern counties; the only rise in the south was in Dorset 35.

Variations in the notifications of whooping-cough were small the largest being a rise of 39 in Yorkshire West Riding. Five counties accounted for three-quarters of the total notifications of diphtheria: Lancashire 26 (Liverpool C.B. 14), London 11, Warwickshire 8, Cheshire 8, and Durham 8.

Of the 18 cases of typhoid 7 were notified in Bedfordshire Biggleswade R.D. The increase in the notifications of dysentery was due to outbreaks in Lancashire, where 217 cases were notified (Ince in Makerfield U.D. 111, Abram U.D. 58, Hindley U.D. 28). The only other centres of dysentery of any importance were London 16 (Kensington 10) and Bedfordshire, Biggleswade R.D. 10.



In *Scotland* there were increases in the notifications of measles 16 and dysentery 10. The chief centres of dysentery were Glasgow 41, Dundee 13, and Lanark county 10. In Lanark county, where 9 cases occurred in the preceding week, 4 more cases of paratyphoid B were notified.

In *Eire* decreases were recorded in the notifications of whooping-cough 40 and diarrhoea and enteritis 13, while an increase of 24 was reported for measles. There was a decrease of 25 in the notifications of diarrhoea and enteritis in Dublin C.B., but a rise occurred in the remainder of the country. The rise in the incidence of measles was contributed by Waterford C.B., where the notifications rose from 24 to 42.

In *Northern Ireland* there was a rise of 59 in the notifications of scarlet fever, and there were decreases in the incidence of whooping-cough 24 and measles 10. In Belfast C.B. the notifications of scarlet fever increased by 46.

Week Ending October 15

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,844, whooping-cough 875, diphtheria 85, measles 992, acute pneumonia 354, cerebrospinal fever 29, dysentery 179, paratyphoid fever 13, typhoid fever 14. The notifications of acute poliomyelitis, 418, and acute polio-encephalitis, 45, reached a new high level and were 78 and 11 respectively above the previous highest returns of this year.

SAFETY and CERTAINTY

For initial digitalisation or for maintenance, Digoxin produces the desired result quickly, safely and with certainty. Being a single crystalline glycoside of definite composition and potency, it ensures a degree of accuracy unattainable with digitalis leaf products. Orally, Digoxin is effective in a few hours; intravenously, in a matter of minutes. It is particularly suitable for maintenance in the ambulant patient because the dose may be adjusted precisely, and risk of toxic effects is reduced, 'Tabloid' brand Digoxin, 0·25 mgm., for oral use; 'Wellcome' brand Sterile Alcoholic Solution of Digoxin (for the preparation of Injection of Digoxin).

DIGOXIN 'B.W.&CO.'

BURROUGHS WELLCOME & CO. (THE WELLCOME FOUNDATION LTD LONDON

In the Service...

Research

The House of Wander continues to maintain its advanced position in pharmaceuticals and quality food products because strict standardization of all ingredients during manufacture is backed by constant control and research in its extensive Research Laboratories.

In Quality

The Wander research chemists have made important contributions in the fields of dietetics, nutrition and vitamins. Devoted constantly to the specialized study of food research, their wide experience and up-to-date laboratory facilities ensure that the quality of *Malt Extract and Cod Liver Oil* (*Wander*) is of the highest obtainable standard—in fact, its vitamin content exceeds that of the analogous B.P. preparation.

The special consideration of physicians when prescribing a malt and oil preparation is that of vitamin values. Comparative studies prove that to prescribe "Wander Brand" is to specify malt extract and cod liver oil of the finest possible quality.

℞ Malt & Oil
(WANDER)

In the Service of Medicine

Meticulous control and advanced laboratory work maintain 'Wander' Brand in the forefront of its class. Moreover, with all its special advantages, 'Wander' Brand costs no more than some malt and oil preparations with a lower vitamin content. *And since its vitamin content exceeds B.P. standards, it may be prescribed without restriction for therapeutic purposes on N.H.S. scripts.*

Concessionary Offer

TO MEMBERS OF THE MEDICAL PROFESSION

ELECTRIC WARMING PADS AND BLANKETS

THERMOSTATICALLY CONTROLLED
FULLY GUARANTEED FOR ONE YEAR

DENHAMS (NCH) LTD., makers of Norvic Electric Warming Pads and Blankets, take pleasure in announcing that they are able to repeat their last season's Concessionary Offer to Members of the Medical Profession at even more advantageous prices:

NORVIC

Single-Heat Pads	32/6
Multi-Heat Pads	44/6
Single-Heat Blankets ..	87/6
Multi-Heat Blankets	105/-

All prices include P. Tax and free delivery by Registered Parcel Post.

To assist in prompt execution of your order please write name and address clearly in block letters.

☆ Please note that the above offer only applies if order is passed directly to the makers

Illustrated leaflet on application

for prolonged local medication

Penicillin Chewing Gum A&H presents penicillin incorporated in a base predominantly mint-flavoured and designed to maintain the potency of the medicament.

When chewed slowly it provides an effective concentration of penicillin in the mouth for three to four hours. It is thus the preparation of choice in the treatment of Vincent's infection, tonsillitis and other infections due to penicillin-sensitive organisms within the buccal cavity.

PENICILLIN CHEWING GUM A&H

In packets of six pieces, each piece containing 5,000 i.u. penicillin (calcium salt).

ALLEN & HANBURYS LTD. LONDON, E.2

A Dietary Supplement for Invalids

Invalids who have to live on a restricted diet for prolonged periods are sometimes unable to take sufficient quantities of the foods containing vitamins of the B complex; a shortage of these vitamins, may, therefore, ensue.

In such cases Marmite, which contains essential, naturally-occurring vitamins of the B_2 group, is often prescribed to make up for a suspected deficiency of these vitamins. Moreover, Marmite stimulates the appetite and can easily be given as a pleasant drink made with hot milk or water.

MARMITE

yeast extract

Jars: 1-oz. 8d., 2-oz. 1/1, 4-oz. 2/-, 8-oz. 3/3, 16-oz. 5/9

Obtainable from Chemists and Grocers

Special terms for packs for hospitals, welfare centres and schools

Medical News

Honorary F.A.C.S.

Sir James Learmonth, Professor of Surgery at Edinburgh University, has been made an Honorary Fellow of the American College of Surgeons. The ceremony was performed at the end of the 35th Congress of the College.

British Trust for Social Studies

The purpose of this Trust is to encourage social research of scientific and practical importance by making small grants for particular projects. The recipient of a grant will be expected to produce within an agreed period a paper of 5–7,000 words setting out the results of the research in a way that can be understood by intelligent non-technical readers. The material presented must be original or based on sources not readily accessible to such readers. The papers so produced will be at the disposition of the Trust for publication, but any payment accruing from publication will be remitted to the author of the paper. Importance is attached to the style of presentation, the need for lucidity of expression, and the avoidance of unnecessary technical terms or mathematical refinements. Applicants must submit a specimen of their written work, published or unpublished. Grants will not normally be made to those who can carry out the research in the course of their regular work; they are intended to help the freelance investigator and those who are well placed for social observation but who would have to work up the material in their spare time. Grants will be for not less than £20. Application forms may be obtained (by post only) from Miss Marion Nuttall, Secretary, British Trust for Social Studies, 16, Queen Anne's Gate, London, S.W.1.

Royal College of Obstetricians and Gynaecologists

The Royal College of Obstetricians and Gynaecologists has arranged postgraduate courses of advanced lectures for those studying the special practice of obstetrics and gynaecology to be given in the College House (58, Queen Anne Street, London, W.) on November 4 and 5, and November 18 and 19. The lectures have been arranged as follows: first course, Friday, November 4, 12 noon, Mr. Leslie Williams, "Post-operative Venous Thrombosis"; 3 p.m., Professor J. F. Cunningham, "Secondary Abdominal Pregnancy"; 5 p.m., Mr. John Howkins, "Mayo's Vaginal Hysterectomy in the Treatment of Prolapse"; Saturday, November 5, 9.45 a.m., Dr. Graham M. Bull, "Treatment of Anuria"; 11.30 a.m., Mr. D. H. MacLeod, "Endometriosis." Second course, Friday, November 18, 12 noon, Dr. A. Rae Gilchrist, "Heart Disease in Pregnancy"; 3 p.m., Mr. Hugh C. McLaren, "The Menopause"; 5 p.m., Sir William Gilliatt, Miss Josephine Barnes, and Mr. J. A. Stallworthy, "Any Questions?"; Saturday, November 19, 9.45 a.m., Mr. Stanley A. Way, "Advances in the Treatment of Carcinoma of the Female Genital Tract"; 11.30 a.m., Professor C. H. G. Macafee, "Hydramnios." The fees are: course of ten lectures, £3 3s.; one week-end course, November 4 and 5, or November 18 and 19, £2 2s.; single lecture, 10s. 6d. Tickets, without which there is no admission, are obtainable from the secretary.

International Health Control

The Public Health Committee of the Brussels Treaty Permanent Commission, which includes representatives of Britain, Belgium, France, Holland, and Luxembourg, held its fourth session in Luxembourg on October 11–13. The committee decided on January 1, 1950, as the date by which regulations should be put into force to enable the five countries to be treated as a single territory for the public health control of sea and air traffic.

Correction of Medical Register

Voting papers for the forthcoming election of one member of the General Medical Council to represent the registered medical practitioners resident in England were issued on October 25 to all practitioners having registered addresses in England. The authorities of the Council would be glad if any such practitioner who has not received a voting paper would communicate immediately with the office of the Council (44, Hallam Street, London, W.1), whether or not he proposes to vote in the election, in order to ascertain that his address is correctly entered in the *Medical Register*.

Special Diets for Invalids

The Ministry of Food announces that patients suffering from acute or convalescent steatorrhoea (including coeliac disease and tropical sprue) who are entitled to half-cream National dried milk may, if they wish, take half-cream proprietary infant milk food instead. The maximum allowance remains at one tin a week.

Photographic Exhibition at Bristol

The exhibition of medical photography held by the Medical Group of the Royal Photographic Society in July in London has been transferred to the Royal Infirmary, Bristol, where it will be on view from October 31 to November 12 from 10 a.m. to 5 p.m., and on Saturdays from 10 a.m. to 1 p.m. The exhibition was reviewed in the *Journal* of July 9 (p. 93). The object of the Medical Group, whose chairman is Sir Cecil Wakeley, P.R.C.S., is to promote the use and advancement of photography in all branches of medical science. The exhibition is being held at Bristol under the auspices of Professor Milnes-Walker.

The Osler Club

A meeting of the Osler Club was held on October 21 at the Wellcome Research Institution, London, through the courtesy of Dr. C. H. Kellaway, F.R.S., Director of the Institution. A paper on "Jenner—Author and Letter Writer" was read by Mr. W. R. Le Fanu, librarian of the Royal College of Surgeons. Jenner considered himself a dilatory letter-writer, but Mr. Le Fanu was able to quote from a number of his letters showing how keen were his powers of observation as a naturalist and how delightful his style in describing minutely what he observed. After the publication of the *Inquiry* in 1798 Jenner had written five successive pamphlets recording subsequent experiments and improvements in technique and explaining the apparent failure of vaccination in some cases. Professor G. S. Wilson, of the Public Health Laboratory Service, spoke of the effect of Jenner's work on subsequent developments in preventive medicine. The importance of controlling the spread of infection had been understood long before the causative agent was discovered. Pasteur's realization of the mechanism of vaccination had led him to work on chicken cholera and anthrax and to the establishment of the principle that the pathogenic properties of a virus could be attenuated. Professor Wilson mentioned the doubts which have arisen in recent years about the efficacy of vaccines in certain infectious diseases, and he emphasized the need for full-scale field trials of B.C.G. Vaccination was not something to be accepted in every disease just because it had proved so successful in the case of smallpox. Jenner had been fortunate in having discovered a perfectly attenuated virus. Dr. E. A. Underwood, Director of the Wellcome Historical Medical Museum, pointed out that Jenner's work had a scientific background. He was not the discoverer of vaccination—others had preceded him—but he had started out with the intention of establishing a permanent working principle, based upon experiment. He had appreciated that protection could be passed on from one to another. Dr. Underwood briefly described the Wellcome Historical Medical Library, which was then opened for inspection. Among the books exhibited were a collection of mediaeval manuscripts, books on the Great Plague of 1665, and some early herbals. Harvey's *De Motu Cordis*, 1628, was displayed beside a well-printed Russian translation of the same work published by the Soviet Academy of Science as recently as 1948.

Wills

Dr. Henry Richard Belcher Hickman, for many years lecturer in physiology at Bristol University, left £25,135. Dr. George Edward Walker Henderson, formerly of Scone, Perthshire, left £17,317. Dr. Robert Gordon Strange, of Hampstead, N.W.3, left £24,992.

COMING EVENTS

University College Hospital

The annual meeting of University College Hospital will be held at University College Hospital Medical School, University Street, London, W.C., on Tuesday, November 1, at 5.30 p.m., when the chairman of the board of governors, Major-General Sir Harold Wernher, will present the annual report of the activities of the hospital, including St. Pancras Hospital and the Hospital for Tropical Diseases. Members of the public are invited to attend the meeting.

Royal London Homoeopathic Hospital

A reception to commemorate the centenary of the Royal London Homoeopathic Hospital will be held in the Great Hall, B.M.A. House, Tavistock Square, London, W.C., on Wednesday, November 2, at 8.30 p.m.

Electronic Instruments

A symposium on electronic instruments in research and industry will be held by the Scientific Instrument Manufacturers Association on November 2–4 at the Examination Hall, 8–11, Queen Square, London, W.C.1. Particulars may be obtained from the association at 17, Princes Gate, London, S.W.7.

Maudsley Lecture

The twenty-fourth Maudsley Lecture will be delivered by Dr. W. Grey Walter before the Royal Medico-Psychological Association at the Royal Society of Medicine, Barnes Hall, 1, Wimpole Street, London, W., on Thursday, November 3, at 2.15 p.m. His subject is "The Function of Electric Rhythms in the Brain." Psychiatrists and other medical practitioners, psychologists, and members of the legal profession, teachers, and students, and all interested are invited to attend the lecture. Admission is without ticket.

Welsh Region Consultants and Specialists

The annual meeting of all the consultants and specialists in the Welsh Hospital Region will be held at the Cardiff Royal Infirmary on Sunday, November 6, at 2.30 p.m. The main business of the meeting will be to consider the report of the honorary secretary on the activities of the regional committee for the past year and the report of the representatives of the committee on the Central Consultants and Specialists Committee. The meeting will also re-elect the regional committee for the ensuing year.

Conference on Health Education

The Central Council for Health Education will hold a conference at the Central Hall, Westminster, London, S.W.1, on November 8–9. It will be opened by Lord Woolton, president of the Central Council, and will be on the objects and methods of health education. The conference fee is 21s., and information may be obtained from the Central Council at Tavistock House, Tavistock Square, London, W.C.1.

d of Hospital Librarians

he Guild of Hospital Librarians will hold a conference "The Hospital Librarian in the Children's Ward" at Chaucer House, Malet Place, London, W.C.1, on November 9 at 2.30 p.m. Dr. Letitia Fairfield will be in the chair. Particulars may be obtained from the honorary secretary of the guild at the Central Library, Bexleyheath, Kent.

Lewisham Hospital Group

The Lewisham Group Hospital Management Committee will hold a meeting at Lewisham Hospital on November 11 at 7.30 p.m. to make public the activities of the group. The chairman will describe the group's work during the period July 5 to December 31, 1948, and there will be opportunity for questions and discussion.

S.E. Metropolitan Regional Tuberculosis Society

A general meeting of the South-East Metropolitan Regional Tuberculosis Society will be held at Grove Park Hospital, Marvels Lane, Lee, S.E., on November 12, at 10 for 10.30 a.m., when papers will be read by Dr. M. N. Nagley, Dr. G. Beven, and Mr. Alistair Gunn. There will also be a demonstration of mass miniature radiography films. The clinical meeting will be followed by the annual general meeting at 3 p.m.

Psychological Films

The Scientific Film Association will hold a symposium on "Problems in Making Psychological Films" at the Wellcome Foundation Institute, 183, Euston Road, London, N.W.1, on November 16 at 7 p.m. Colonel B. Ungerson will be in the chair. Admission will be by ticket only, which can be obtained from the association at 4, Great Russell Street, London, W.C.1

Empire Rheumatism Council

The Empire Rheumatism Council has arranged an autumn week-end postgraduate course to be held at the Apothecaries' Hall, Blackfriars Lane, Queen Victoria Street, London, E.C., on Friday, Saturday, and Sunday, November 18, 19, and 20, with the following programme: November 18, 4.30 p.m., Dr. W. S. C. Copeman, "Recent Advances in the Treatment of the Rheumatic Diseases"; 5.30 p.m., Dr. G. D. Kersley, "Gout." November 19, 10 a.m., Dr. F. Dudley Hart, "Spondylitis"; 11.15 a.m., Dr. H. J. Gibson, "Pathology of the Rheumatic Diseases"; 2 p.m., Dr. E. G. L. Bywaters, "Juvenile Rheumatism"; 3 p.m., Dr. W. S. Tegner, "Rheumatoid Arthritis—Recent Developments"; 4.30 p.m., Dr. Oswald Savage, "Non-articular Rheumatism." November 20, 10 a.m., Dr. Hugh Burt, "Physical Methods in the Treatment of the Rheumatic Diseases"; 11.15 a.m., Mr. W. D. Coltart, "Orthopaedic Aspects of the Rheumatic Diseases." The fee for the course is £2 2s., and entries (limited to 100) must reach the general secretary of the council, Tavistock House North, Tavistock Square, London, W.C.1, at least one week before the course opens.

SOCIETIES AND LECTURES

Monday

LONDON UNIVERSITY.—At University College (Chemistry Theatre), Gower Street, London, W.C., October 31, 5.15 p.m., "*The Chemistry of the Transuranics and Other Newly Discovered Elements*," by Professor H. J. Emeleus, F.R.S.

LONDON UNIVERSITY.—At Westminster Medical School (Meyerstein Lecture Theatre), Horseferry Road, London, S.W., October 31, 5.30 p.m., "*The Indispensability of Biologically Labile Methyl Groups in the Diet and Transmethylation*," by Professor V. du Vigneaud (Cornell University Medical College).

UNIVERSITY COLLEGE, Gower Street, London, W.C.—October 31, 4.45 p.m., "*Technique and Applications of Tissue Culture*," by Dr. Charity Waymouth.

Tuesday

DONCASTER MEDICAL SOCIETY.—At Parkinson's Café, Doncaster, November 1, "*Puerperal Fever*," by Dr. W. Lomax, preceded by dinner at 7.45 for 8 p.m. Joint meeting with Doncaster Division of B.M.A.

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—November 1, 5 p.m., "*Arsenic and the Skin*," by Dr. W. J. O'Donovan.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, London, W.C.—November 1, 2.15 p.m., "*The Respiratory Tract in Infectious Diseases*," by Dr. E. H. R. Harries.

Wednesday

LONDON COUNTY MEDICAL SOCIETY.—At Whittington Hospital, Highgate Hill, N., November 2, 3 p.m., clinical meeting.

LONDON UNIVERSITY.—At Westminster Medical School (Meyerstein Lecture Theatre), Horseferry Road, London, S.W., November 2, 5.30 p.m., "*The Indispensability of Biologically Labile Methyl Groups in the Diet and Transmethylation*," by Professor V. du Vigneaud (Cornell University Medical College).

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—November 2, 3.30 p.m., "*The Preparation of Food for Human Consumption*," by Dr. A. G. G. Thompson.

ROYAL MICROSCOPICAL SOCIETY, B.M.A. House, Tavistock Square, London, W.C.—November 2, 6 p.m., meeting of Biological Section, "*Inexpensive Phase Microscopy*," by Dr. G. A. Harrison and Mr. M. G. L. Curties.

SOCIAL PSYCHOTHERAPY CENTRE, 7, Fellows Road, London, N.W.—November 2, 5 p.m., "*Instructional Group Psychotherapy, I*," by Dr. E. N. Snowden.

SOCIETY OF PUBLIC ANALYSTS.—At Chemical Society, Burlington House, Piccadilly, London, W., November 2, 6.45 p.m., ordinary meeting. "*Some Recent Advances in Water Examination*," short contributions on this subject by Messrs. J. H. Hamence, C. B. Taylor, Roy C. Hoather, G. U. Houghton, and J. E. Houlihan. A discussion will follow.

Thursday

Faculty of Homoeopathy.—At Royal London Homoeopathic Hospital, Great Ormond Street, London, W.C., November 3, 5 p.m., *"Homoeopathic Experiences at Home and Abroad,"* by Dr. Q. Muriel F. Adams.

Honyman Gillespie Lecture.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, November 3, 5 p.m., *"G.P.I.: Its Juvenile and Senile Types,"* by Dr. R. M. Stewart.

Institute of Dermatology, 5, Lisle Street, Leicester Square, London, W.C.—November 3, 5 p.m., *"Nutritional Disorders of the Skin,"* by Dr. B. Russell.

Institute of Laryngology and Otology, 330, Gray's Inn Road, London, W.C.—November 3, 2.15 p.m., *"The Surgical Treatment of Otosclerosis,"* by Dr. I. Simson Hall.

London University.—At Royal Society of Medicine, 1, Wimpole Street, London, W., November 3, 5 p.m., *"Tonsillar Function: A Review of the Evidence,"* Semon Lecture by Mr. A. J. Wright (University of Bristol).

Royal [illegible]n.—At Royal Society of Medic[illegible] London, W., November 3, 2.1[illegible] *Rhythms in the Brain,"* 24th Maudsley Lecture by Dr. W. Grey Walter.

Society for Cultural Relations with the U.S.S.R.—At University of London Institute of Education, Malet Street, W.C., November 3, 7.30 p.m., *"Pavlov, Scientist and Man: His Place in the History of Civilization,"* by Mr. J. G. Crowther.

St George's Hospital Medical School, Hyde Park Corner, London, S.W.—November 3, 4.30 p.m., lecture-demonstration: *"Neurology,"* by Dr. A. Feiling.

Wrexham and District Clinical Society.—At Wynnstay Hotel, Wrexham, November 3, *"Some Reflections from an Allergy Clinic,"* by Dr. Cyril Clarke. Preceded by dinner at 7.30 p.m.

Friday

Maida Vale Hospital for Nervous Diseases Medical School. Maida Vale, London, W.—November 4, 5 p.m., clinical demonstration by Dr. Russell Brain.

Royal Institution, 21, Albemarle Street, London, W.—November 4, 9 p.m., *"The Dimensions of Animals and their Muscular Dynamics,"* by Professor A. V. Hill, F.R.S.

Royal Institute of Philosophy, 14, Gordon Square, London, W.C.—November 4, 5.15 p.m., *"Neutral Monism and the Philosophy of Nature,"* by Professor H. H. Price.

Royal Medical Society, 7, Melbourne Place, Edinburgh.—November 4, 8 p.m., *"The Aetiology and Treatment of Ulcerative Colitis,"* by Mr. C. W. Mercer.

Society of Anaesthetists of South Wales.—At Park Hotel, Cardiff, November 4, 7 p.m., dinner-meeting. Address by Dr. John Gillies.

University College, Gower Street, London, W.C.—November 4, 5.15 p.m., *"Transmission of Excitation in Nerve and Muscle,"* by Dr. Bernhard Katz.

Saturday

Institute of Laryngology and Otology, 330, Gray's Inn Road, London, W.C.—November 5, 11.15 a.m., *"Examination and Treatment of Children, particularly those of School Age,"* by Mr. Henry Forster.

Institute of Obstetrics and Gynaecology.—At Postgraduate Medical School of London, Ducane Road, W., November 5, 11 a.m., *"Puerperal Infection,"* by Dr. A. M. Ramsay.

York Medical Society.—At 17, Stonegate, York, November 5, 8.30 p.m., *"Some Diseases of the Skin of Interest to General Practitioners,"* by Dr. H. W. Barber.

APPOINTMENTS

Lord Nathan of Churt has been appointed a Crown Representative on the General Medical Council.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Anderson.—On October 13, 1949, to Doris (née Twiddy, S.R.N., S.C.M.), wife of Dr G. Anderson, 192, Hawthorn Road, Birmingham, 22C., a son

Blench.—On October 8, 1949, at the Queen Elizabeth Hospital, Birmingham, to Dr Pearl Blench (née Evans) and Dr. Athelstan Blench a daughter

Burchill.—On October 19, 1949, to Mrs. K. Burchill (née Birkhead), wife of Dr K. Burchill, 132, Moorside Road, Davyhulme, Manchester, a daughter.

Clements.—On October 14, 1949, to Megan, wife of Dr M. W. L. Clements, 149 Warwick Road, Kenilworth, a son.

Geddie.—On October 9, 1949, at Rubislaw Nursing Home, Aberdeen, to Margaret (née Cook), wife of Dr. John M. Geddie, a daughter.

Markowe.—On October 15, 1949, at Garrett Anderson Maternity Home, to Helen (née Tell), wife of Morris Markowe, M.D., a daughter—Lesley.

MARRIAGE

Scott—Wilson.—On October 1, 1949, at All Saints Church, Gosforth, Newcastle-upon-Tyne, Cedric Mathieson Scott M.B., B.S., of Hartlepool, to Gwendoline Doxford Wilson of Fawdon Park, Newcastle-upon-Tyne.

DEATHS

Cassidy.—On October 22, 1949, at 42, Montagu Square, London, W., Sir Maurice Alan Cassidy, G.C.V.O., C.B., M.D., F.R.C.P.

Hawthorne.—On October 24, 1949, at 113, New Church Road Hove, Charles Oliver Hawthorne, M.D., D.Sc., LL.D., F.R.C.P., late of 63, Harley Street, London, W.

Woods.—On October 23, 1949, at 5, Albert Terrace, Douglas, Isle of Man, Lionel Dudley Woods, O.B.E., L.R.C.P.&S.I., aged 63.

Any Questions ?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Amphetamine Sulphate

Q.—(*a*) *What are the toxic effects of amphetamine sulphate? Can these arise with normal dosage? Are any risks associated with long-continued use of moderate doses?* (*b*) *Is amphetamine sulphate desirable as a slimming agent? Is it better or safer than thyroid? Should not all slimming be done by the control of intake of food alone?*

A.—(*a*) The common toxic effects of amphetamine sulphate are: restlessness, insomnia, and irritability; palpitation, extrasystoles, and rarely a persistent rise in blood pressure; dryness of the mouth, anorexia, and flatulence. These symptoms may be experienced to a mild extent, even with moderate dosage, by some individuals who are peculiarly sensitive to the drug, but subside as soon as it is withdrawn. There is little risk associated with long-continued administration of moderate doses. The danger of inducing or aggravating hypertension by its use is very slight, though the drug should probably be avoided by hypertensive subjects and by those suffering from coronary disease and cardiac arrhythmias. A very few unstable individuals who have experienced the euphoria which amphetamine induces may be tempted to increase the dose and thus develop an addiction with chronic hyperexcitability alternating with melancholia. As tolerance and severe craving are not features of the addiction, withdrawal is easy. The usual dose in the treatment of obesity is 5 mg. three times a day before meals, but if the last dose is taken later than 4 p.m. sleeplessness may result.

(*b*) Amphetamine and thyroid act quite differently in assisting weight-reduction: the former diminishes the desire for food and so helps a patient to avoid eating more than has been prescribed; the latter stimulates metabolism and thus increases the rate of combustion of food. Neither is dangerous if it is properly prescribed and the patient is supervised while taking it. The evil effects of overdosage with thyroid are more serious than those produced by overdosage with amphetamine, and last longer after withdrawal of the drug. The majority of people lose weight satisfactorily on a sub-caloric diet alone without the need to prescribe either drug, which should never be used as a substitute but only as an adjuvant to dieting. Properly employed, however, both drugs may be valuable in certain cases. Amphetamine may be useful, particularly in the early stages of treatment, for patients who complain of extreme hunger and depression as the result of a low-calorie diet; whereas thyroid is more valuable in the later stages of treatment, when the weight loss due to careful dieting may become unduly slow owing to the reduction in metabolic rate which invariably occurs on low-calorie intakes, and which is shown in its greatest degree in the completely fasting individual.

Chemical Sympathectomy

Q.—*What exactly is "chemical sympathectomy"? To what extent and in what kind of cases can it replace surgical sympathectomy? Does it ever provide a form of therapeutic test which would indicate the need for sympathectomy?*

A.—Sympathetic nerve impulses may be temporarily interrupted, either locally by procaine injection of the ganglia and nerve trunks or, generally, by systemic administration of autonomic ganglion blocking agents such as tetraethylammonium bromide. In peripheral vascular thrombosis or embolus, sympathetic nerve block, by releasing vascular tone in the collateral circulation, may prove a valuable adjunct in conservative treatment. By similar vasodilator action, procaine block gives an indication of the benefit to be expected from surgical sympathectomy in such diseases as thrombo-angiitis obliterans, the

response being poor when the obstruction is largely organic and involves the whole vascular tree. In the sympathetic dystrophies, such as causalgia and painful phantom limb, dramatic relief of pain may follow procaine block, the beneficial effect long outlasting the period of chemical action. For details of injection technique the larger works must be consulted, and it is advisable to practise first on the cadaver, using coloured injection solutions, since sympathetic trunks lie in contact with several vital structures.

In assessing the probable response of the hypertensive patient to sympathectomy, the "sodium amytal" sedation test is preferable to any measure more directly aimed at interference with sympathetic activity. When the aim of treatment is interruption of the renal shunt mechanism as in the management of some cases of anuria, spinal analgesia is probably the easiest method of producing temporary bilateral sympathetic denervation of the kidneys. Tetraethylammonium bromide can be given intramuscularly to bed patients only and blocks all autonomic ganglia. It produces, amongst other effects, postural hypotension. Good results are claimed for its use in Buerger's disease and causalgia, and it has been used with some success in the treatment of pre-eclamptic toxaemia of pregnancy. Work in this field, however, must still be regarded as being in the experimental phase.

Breathing through a Closed-circuit Apparatus

Q.—*The use of the closed circuit and absorption of carbon dioxide entails gross interference with the normal mixture of gases in the pulmonary alveoli. Is this harmful? What are the subjective sensations when the closed-circuit atmosphere without any anaesthetic agent is breathed for, say, an hour?*

A.—So long as the patient breathes spontaneously, the use of an efficient closed-circuit apparatus entails no "gross interference with the normal mixture of gases" in the alveoli. In fact, this method reproduces conditions of normal respiration more faithfully than any other form of administration. Since practically all the exhaled carbon dioxide is removed, the inspiration contains only the minutest quantity of this gas, as is the case in normal life. Resistance to breathing in a well-designed apparatus should be so small as to have no observable effect.

In order to answer the last part of the question the writer himself breathed from a Coxeter–Mushin absorber for an hour. A colleague made frequent observations of the pulse rate, the character of respiration, and the colour and condition of the skin. The only subjective symptoms were the discomfort of the mask pressure on the face (necessary to obviate leakage), the initially unpleasant smell of rubber, a slight but not uncomfortable sense of warmth, and a sense of great boredom during the proceedings. The pulse remained steady at 60, and the respirations were rather shallow with an occasional deep breath. At the end of the experiment no after-effects whatever were observed, normal activities being immediately resumed.

Progesterone Treatment of Rheumatoid Arthritis

Q.—*Has progesterone proved effective in rheumatoid arthritis? What is the usual dosage, and what is the rationale of this treatment?*

A.—Progesterone has been used experimentally in the treatment of rheumatoid arthritis, but conflicting reports have been received regarding its efficacy. Probably it is capable of producing some improvement in certain cases. No standard dosage has been laid down. The rationale is based on the observed fact that sufferers from this disease are often much benefited if they become pregnant. Progesterone is the chief ovarian secretion in the latter part of pregnancy.

Clonorchiasis

Q.—*What is the treatment of clonorchiasis?*

A.—Treatment of clonorchiasis is often unsatisfactory. Gentian violet and sodium antimony tartrate are the drugs of choice; chrysotherapy is of very doubtful value. In resistant cases it might be worth while trying the effect of emetine in view of this drug's action against other trematodes.

Cord Round the Neck

Q.—*A woman aged 29 was delivered of a stillborn child at full term. Death was apparently due to the cord being looped three times round the neck. The patient is now pregnant again. Is there a greater liability than in other cases of the same complication occurring?*

A.—Cord round the neck which, as the head descends, tightens to such an extent as to interfere with foetal circulation can certainly cause stillbirth. It is, however, a rare cause of foetal death and a chance occurrence which is not specially liable to recur in any one case. If other causes for the stillbirth have been excluded the patient can be reassured.

Pruritus

Q.—*Is there any treatment for severe pruritus of the scalp? The itching is worst after the patient has been in bed half an hour and on rising in the morning. The scalp is clean and free from rash or parasites, nits, or swollen glands.*

A.—In the absence of general vascular or metabolic disease, pruritus capitis, like pruritus ani, is generally nervous in origin. Perchloride of mercury (1 in 1,000) in spirit and water with fractional doses of *x* rays locally, and phenobarbitone ¼ to ½ gr. (16 to 32 mg.) internally, are suggested. Rubbing and scratching and vigorous treatments are to be avoided. Gentle washing once or twice a week should be sufficient to keep the scalp clean.

NOTES AND COMMENTS

Glasses in Myopia.—Dr. D. PRIESTLEY SMITH (Birmingham) writes: I am glad to see what Mr. A. Seymour Philps says (October 8, p. 824). After many years of ophthalmic practice I am satisfied that in myopes of moderate degree glasses are needed only for the definition which they give at the time: that is to say, glasses do not prevent myopia from increasing, and there is no need, on that score, for them to be worn all the time. Many boys and girls only need them in the class-room so as to read the blackboard. Others choose to keep them on all day so as not to miss the details of the world around them. But, as regards the welfare of the eyes, it does not matter which they do. In high myopia the question does not arise, for the patient cannot do anything without his glasses.

Threadworms in Infants.—Dr. W. R. COLE (Bristol) writes: Your answer in "Any Questions?" (September 17, p. 661) on treatment of threadworms, wherein you advise even hospital admission in order to administer the gentian violet capsules, would hardly be well received by those responsible for allotting hospital beds. Treating this condition in my own critical household, I successfully deceived the young patient (who had already bitten one, and so tasted and seen the rather frightening result) by concealing the capsule in a soft-centred sweet. I have often advised this since, but unfortunately the older child usually discovers this after a few times. Surprisingly you did not mention "diphenan" 7½-gr. (0.5-g.) tablets (one-quarter tablet t.d.s. for ages under 2 years), which are quite tasteless and crushed with sugar will deceive all, the only snag being the castor oil recommended at the end of the week's course.

Corrections

Dr. STUART LAIDLAW (Glasgow) writes: In your issue of October 8 (p. 808) you state in the paragraph of the second column commencing "Dr. Stuart Laidlaw (Glasgow)" that the waiting-list for sanatorium beds is 16,000 in Glasgow. This should have read 1,600.

A printer's error caused the name of the new president of the Medical Defence Union, Mr. Ivor Back, to be printed as Mr. Ivor Black in the *Journal* of October 1 (p. 752).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY OCTOBER 29 1949

THE SECRETARY REPORTS

INEXCUSABLE DELAY

The two most significant items in the week's news are the intimation by the Ministry that it will not be able to reply before the Conference of Local Medical Committees to the representations made to it on behalf of the general practitioners in the Service and, secondly, the Prime Minister's announcement that except in the case of old-age pensioners a charge of up to 1s. will be made to the patient for each prescription under the National Health Service.

No doubt much will have been said on the first point in the Conference of Local Medical Committees, which will meet before these words appear. While it is recognized that the criticisms of the representatives of the General Medical Services Committee rendered inevitable the rewriting of a formidable statistical document, this cannot explain or excuse the long delay in replying to a case put forward more than six months ago. After all, the essence of the first part of our claim was that the calculations made at the inception of the Act were inaccurate and that the size of the medical pool should be adjusted to meet those inaccuracies. The General Medical Services Committee is holding a special meeting on the afternoon before the conference to consider the position created by this reply.

Prescription Charge

On the point of the prescription charge I have, by the nature of things, to write immediately after the Prime Minister's speech without knowing the detailed method of the application of the charge. His actual words are worth studying.

"We propose to make a charge of not more than 1s. for each prescription under the National Health Service. (Some Ministerial cries of "Shame!") The purpose is to reduce excessive, and in some cases unnecessary, resort to doctors and chemists of which there is evidence which has for some time troubled the Minister of Health and the Secretary of State for Scotland. (Ironical Opposition laughter.) The resultant saving will contribute about £10,000,000, although this is not the primary purpose of the charge. Arrangements will be made to relieve old-age pensioners of this charge for prescriptions."

Generally speaking, this development will probably be welcomed by general practitioners, not necessarily because of any merit it may or may not possess, but because it may lead to a lessening of the very heavy burden of work. This lessening, it will be widely felt, is something which had to be achieved somehow or other. But that is not to pass comment on the method, which involves a fundamental departure from a system which has been in operation since 1913. A good deal depends on the details, yet unrevealed, of the administrative steps to be taken to collect the money and on the possibilities of exemption, not only for old-age pensioners, but for poorer or larger families where genuine hardship may result. Presumably the collection will be made by the chemist and not by the doctor, except where the doctor undertakes his own Service dispensing. Clearly the position of the dispensing doctor will need to be carefully watched. It is not clear whether the charge is to be made in respect of prescriptions or scrips. It would appear at first sight to relate to all prescriptions given, whether by the general practitioner or by the specialist in the hospital service. Will the charge be the same for the 6- as for the 24-oz. bottle, for 12 tablets as for 48 tablets? We understand the Ministry of Health is not yet ready with any detailed scheme.

High Costs

This development is an interesting commentary on the attempt which has been made in some quarters to saddle the medical profession with a responsibility for the high cost of drugs and appliances since the introduction of the Service. After all, the declared object was to ensure that medical care should be available to all, and people were urged by the promoters of the Act to make the fullest use of what they called a free Service. The profession urged that the Service should be introduced by stages, beginning with its hospital part. In practice, there has been gross under-estimating both of the psychology of the people and of the financial costs involved. Much of the present difficulty would have been avoided if the Service had been limited to those who needed it and had been brought into being in stages as part of a long-term programme.

SUPERANNUATION FOR PART-TIME SPECIALISTS

OPTING OUT

Details of the conditions under which part-time specialists in contract with hospital boards may opt out of the N.H.S. Superannuation scheme were published in the *Supplement* of August 20 (p. 93). One of the conditions is that those part-time specialists who wish to contract out must do so before November 1, 1949, by giving written notice to the Ministry of Health, Health Services Superannuation Division, Honeypot Lane, Stanmore, Middlesex, on Form S.D. 28A, which is obtainable from regional hospital boards or boards of governors of teaching hospitals.

Some part-time specialists have expressed a wish to defer their decision whether to exercise the option until they receive their permanent contracts. As a safeguard, they should apply to the Ministry of Health before November 1 explaining their position and asking that the application be not confirmed until they are able to inform the Ministry that the permanent contracts have been settled.

COMMITTEE ON PRESCRIBING

RESTRICTIONS TO BE CONSIDERED

The Central and Scottish Health Services Councils, constituted under the National Health Service Acts, have jointly appointed a committee

"to consider and report from time to time whether it is desirable and practicable to restrict or to discourage the prescribing by practitioners giving general medical services under the National Health Service Acts of 1946 and 1947 of

(i) drugs and medicines of doubtful value or of unethical character;

(ii) unnecessarily expensive brands of standard drugs."

The Joint Committee consists of members suggested by the Standing Medical and Pharmaceutical Committees of England and Wales; the Scottish Medical, Pharmaceutical, and General Practitioner Services Advisory Committees; the three Royal Colleges; the Scottish Royal Medical Corporations; the British Medical Association; the British Pharmacopoeia Commission; the Society of Apothecaries.

The names of the members are as follows: Dr. Janet Aitken; Professor Stanley Alstead; Dr. J. A. Brown; Sir Henry Cohen; Professor E. C. Dodds; Professor D. M. Dunlop; Dr. F. Gray; Dr. P. Hamill; Mr. J. C. Hanbury, F.R.I.C.; Dr. G. MacFeat; Professor Chassar Moir; Dr. A. Smith Pool; Mr. J. H. Ramsay, Ph.C.; Dr. W. D. D. Small; Sir Henry Souttar; Mr. D. E. Sparshott, M.P.S.; Dr. J. G. Thwaites; Alderman W. J. Tristram, M.P.S.

At its first meeting the committee elected Sir Henry Cohen as chairman and Professor Dunlop as vice-chairman.

EXTRAVAGANT DEMANDS

Mr. H. Lesser, president of the Executive Councils Association (England), said that he could not condone any extravagant demands on the new Service by the public or any section of it when he addressed the second annual meeting at Bournemouth on October 21. But he was not sure to what extent the case was proved. "If drugs and appliances—including the harmless necessary wig—are being provided in excessive quantities, is it not the doctor who prescribes them?"

Of course they knew that practitioners had their own difficulties. The practitioners' first and proper concern was to establish confidence between themselves and their patients. He considered that only by more co-operation between practitioners and patients could a truly efficient public service be attained. Considerable tact and good will were demanded from executive councils and their staffs in bringing pressure to bear to prevent or remedy weaknesses in the scheme by disciplinary action.

Dr. N. E. Waterfield was elected president in succession to Mr. Lesser.

GENERAL PRACTITIONER REMUNERATION

MEETING DELAYED

The Ministry of Health was unable to meet representatives of the General Medical Services Committee before the Conference of Local Medical Committees was held on October 27.

When a deputation from the G.M.S. Committee visited the Ministry on September 23 to present its case for the increased remuneration of general practitioners the Ministry agreed that the Ministry's statement of the facts on what general practitioners have been paid would need to be rewritten.

A number of false assumptions had been pointed out by the G.M.S. Committee's representatives, and it was agreed that discussions on the inadequacy of the Central Pool could not start until they had been corrected. The Ministry undertook to look into the various points raised, and it was hoped it would have completed the task before the conference was held, but it has been unable to do so. The Ministry has stated that a redraft of its statement will be sent to the committee as soon as possible.

GENERAL PRACTITIONERS IN HOSPITALS

EAST SUFFOLK DISPUTE

At a meeting on October 9 the East Suffolk Local Medical Committee unanimously agreed to the following resolutions:

Maternity Beds.—The East Suffolk L.M.C. is of the opinion that the policy of excluding general practitioners from attending their maternity cases in maternity homes annexed to, or part of, general hospitals is contrary to the best interests of the expectant mothers and in conflict with their entitlement to free choice of doctor.

General Practitioners in Hospitals.—The East Suffolk L.M.C. is dissatisfied with the exclusion of general practitioners from reappointment to general-hospital posts which they have held for many years with complete satisfaction.

The Brook Street Maternity Home at Ipswich is reported (*East Anglian Daily Times*, October 13) to have been redesignated by the regional board as a general hospital, with the result that it will be staffed by the regional board and serve as a maternity annexe to the maternity department of the local general hospital. The effect of this will be that expectant mothers in the maternity home will be denied the services of their general practitioners.

MINISTRY OF SUPPLY

INCREASED FEE FOR EXAMINATIONS

Recently the attention of the Association was drawn to the fact that a fee of only 5s. was being paid for the examination and report on prospective employees of the Ministry of Supply.

Representations have been made to the Ministry concerning the inadequacy of this fee, and the Ministry has now increased the fee to 10s. 6d. where the medical examination is carried out at the doctor's surgery, and 12s. 6d. for such examinations carried out at a Ministry of Supply Establishment, with the addition of travelling allowance at 1s. per mile beyond two miles. The revised fees will be paid for all examinations that have taken place since August 1, 1949.

FEE FOR REPORT

PERSONS OF UNSOUND MIND

As the outcome of representations made to the Prison Commissioners, they have informed the Association that they will pay a fee of £2 2s. for the examination and report on persons remanded in custody where it appears that the person on remand is of unsound mind and a proper person to be detained. The report is required by courts under Sections 24 and 26 of the Criminal Justice Act, 1948.

Mileage allowances at the rate of 1s. a mile after the first two miles will also be paid.

HEARD AT HEADQUARTERS

Lancashire and Cheshire

A process of division and multiplication has been proceeding in the Lancashire and Cheshire Branch. The Branch has been dissolved, and three new ones take its place. The Lancashire and Cheshire Branch for more than a century has been one of the most flourishing in the Association. It has given many outstanding figures to our central affairs, although, strangely enough, it has never produced a chief officer, except one Chairman of Council nearly eighty years ago. The Branch was formed ten days after Queen Victoria came to the throne. Its origin was at Newton, half-way between Manchester and Liverpool, and it was for a time known as the Newton Medical and Surgical Association. It was strictly in alliance with the Provincial Medical and Surgical Association (the earlier name of the B.M.A.), but with true Lancashire independence it refused any pecuniary assistance from the latter body. At first its meetings were held only at Newton, except for one or two at Warrington, apparently from a disinclination to give a

preference to either of the two great cities it included. Its name "Lancashire and Cheshire" was adopted just a hundred years ago, and after that it met at Liverpool and Manchester, but not until 1857 did it spread northwards, for a meeting at Preston. A hundred years ago the Branch had 90 members; fifty years ago it had over 1,000; at the date of its dissolution it had well over 4,000.

Branch Areas

When regional hospital areas were formed there was some suggestion that the Association's organization should be recast in a regional mould. In fact the new Merseyside Branch does cover substantially the Liverpool Hospital Region. Otherwise there does not appear to be any intention to modify the areas of local B.M.A. units to make them conform with regional hospital areas. On the contrary, the present tendency is to modify areas to make them conform with the natural meeting areas of the local profession. This is a sound development, and its effect must be in due course to strengthen the position of the Divisions and Branches.

Treating Oneself

A correspondent complains that doctors in the Health Service are not allowed to be on their own lists. As he points out, the ruling conflicts with the principle that everyone may choose his own doctor. The Ministry refuses to allow it because the General Medical and Pharmaceutical Services Regulations, 1948, say: "A practitioner is required to render to his patients all proper and necessary treatment." Since a doctor could not give himself a general anaesthetic while his appendix is taken out, or treat himself if he were in a coma, he is debarred from being on his list. Logical arrangements are easier to administer than humane ones, but there is a strong case for letting doctors join their own lists. The relationship between doctor and doctor is quite different from that between patient and doctor, and a doctor who has some small infirmity that he could easily treat himself should not be compelled to bother a colleague, whether that colleague is a friend or a competitor.

Questions Answered

Dentistry by General Practitioners

Q.—*Since the beginning of the National Health scheme I find that I sometimes have to undertake emergency dental extractions, the waiting-list for dental treatment being so long and there being no resident dentist in this town. Can any special fee be claimed for these cases?*

A.—The regulations do not permit any special fee for dental treatment carried out by a general practitioner. If the patient is not on the practitioner's list, or that of his partner or assistant, a fee for emergency treatment would be payable.

Fees for Examining Emigrants

Q.—*I have examined an N.H.S. patient, who is on my list, to complete a form for emigration to South Africa. I am informed that the laboratory fee for the required report on the Wassermann test is £1 1s. Is the laboratory entitled to charge the patient a fee? Am I also entitled to charge a fee?*

A.—The work of examining and reporting upon prospective emigrants (including *x*-ray examinations and blood tests) does not come within the scope of the hospital and specialist services provided under Section 3 of the N.H.S. Act. Therefore a member of a hospital medical staff (e.g., radiologist or pathologist) who is asked to furnish a special report in this connexion is entitled to a fee, one-third of which is payable to the hospital if the hospital laboratory or radiological facilities are used.

A general practitioner carrying out the medical examination of an intending emigrant is not debarred from charging the patient a fee for his report by reason of the fact that the person is on his list as a public patient.

Resigned from Health Service

Q.—*Is a doctor who has resigned from the National Health Service and drawn his compensation permitted to engage in private practice only?*

A.—A doctor in these circumstances is permitted to engage in private practice.

Work Outside Full-time Contract

Q.—*I am a full-time orthopaedic consultant under contract with a regional board. I have also been performing a weekly session as orthopaedic consultant to the Ministry of Pensions locally. Am I entitled to a sessional fee for this work?*

A.—Normally, a consultant who has a full-time contract with a regional hospital board is not entitled to perform work other than for his hospital board. If outside work, such as with the Ministry of Pensions, is required, it would be by arrangement between the two authorities

PUBLIC HEALTH COMMITTEE

At the first meeting of the new session of the Public Health Committee of the Association on October 21 a letter was read from Dr. James Fenton intimating that, having retired from the service of the Kensington Borough Council and accepted an appointment as temporary officer at the Ministry of Health, he felt himself compelled to withdraw from the membership of committees which undertook negotiations on salary questions and also not to stand for re-election as chairman of the Public Health Committee, although he wished to remain a member of that committee. The Chairman of Council (Dr. Gregg), who temporarily occupied the chair, spoke of Dr. Fenton's extremely valuable work for the Association, and particularly for that committee, and Dr. R. H. H. Joll, and Dr. J. A. Ireland spoke in similar vein. The committee expressed its gratification that, even though no longer chairman, Dr. Fenton would continue his membership.

Dr. C. Metcalfe Brown, of Manchester, was unanimously elected chairman.

Whitley Machinery

The present position with regard to Whitley machinery was the subject of an oral report by the Secretary (Dr. Charles H. L. He said that a revised draft of the scheme dealing in particular with the membership of the three main committees had gone to the local authority associations, though it might still be some time before the matter was completed. Progress was very slow indeed. The Secretary also discussed with the committee matters which had arisen concerning the representation of the medical profession in the Whitley machinery, and appropriate action was taken.

On the question of the delay it was agreed that the Chairman of Council and the chairmen of the three committees concerned—the Central Consultants and Specialists, the General Medical Services, and the Public Health—should be asked to interview the Secretary of the Ministry as a matter of urgency.

It was agreed to recommend the Council to send to the *Lancet*, the *Medical Officer*, *Public Health*, and the *Medical World* a letter of appreciation of the full co-operation which they had extended, with no small loss of revenue to themselves, during the period of the recent advertisement ban which had obtained until the local authority associations intimated their willingness to participate in the Whitley machinery.

The committee appointed its representatives on the Public Health Subcommittee of the Medical Functional Council for 1949–50. The membership of 13 (including three Scottish representatives) remains the same, except that Dr. F. Hall and Dr. Struthers take the place of Dr. Fenton and Dr. George Buchan, who had intimated that they were no longer available to serve.

Whole-time Officers

The general question of the position and remuneration of whole-time officers whose duties fall partly under a local

will, yet I do suggest that there is no compulsion of any firm to present such an agreement. Surely neither the Medical Practices Committee nor any executive council has any legal power to invalidate such an agreement or to prevent any practitioners on the list of an executive council entering into a formal partnership agreement if they so desire. Surely the only document that it is necessary to make a partnership "officially valid and operative" is a form of partnership agreement duly executed and stamped.

It is imperative that these *ad hoc* bodies that are springing up in the medical world should not be credited with powers or a wider range of activity than they do in fact possess.—I am, etc.,

London, N.W.2. A. N. MATHIAS.

*** The writer is quite correct, but if official sanction is desired to an agreement then the answer given was correct. The word "officially" has caused some confusion.—ED., *B.M.J.*

Payments to Chemists

SIR,—Your correspondent, Dr. K. V. Deakin (*Supplement*, October 1, p. 156), is using a faulty yardstick in his comparison of earnings of chemists for pharmaceutical services provided under the N.H.S. Act with those of the medical profession. He apparently fails to realize that the payments made to chemists include the net cost payments for drugs, medicines, dressings, and appliances and the containers. Taking that factor into account, the gross figures, as quoted by your correspondent, must be reduced by at least 45% and on the average by 50%. Out of the residue the chemist has to meet that part of his establishment and staffing costs which is attributable to the dispensing department. These costs, already high, are continually increasing.

The *net* income of the chemist from N.H.S. pharmaceutical services is manifestly very different from what your correspondent's figures suggest. With his basic contention that the remuneration of the medical profession is inadequate I for one certainly would not quarrel. Probably more than any other section of the community chemists realize the tremendous burden of additional work which the advent of the N.H.S. scheme has thrust on the medical profession, and they have every sympathy with the profession in its difficulties.—I am, etc.,

London, W.C.1. H. NOBLE,
Secretary, The National Pharmaceutical Union.

Status of General Practice

SIR,—Dr. Ian D. Grant (*Supplement*, October 1, p. 155) has very ably shown that the National Health Service gives reward in general practice not for quality but for quantity. He also asserts that the biggest numbers gravitate to the "yes man" who freely acquiesces in the general exploitation by issuing certificates and prescriptions *ad lib.* or according to the dictates of the patient. To a certain extent this is true. Inevitably the system lowers the status of the G.P. to that prevailing in the least attractive industrial practice of the old days.

Pari passu with the deterioration of general practice there is an overall increase of costs. The Minister of Health blames the general practitioner, but the practitioner is pretty helpless, as he is too often forced to acquiesce in the dictates of the patient.

In hospital practice the picture appears no less gloomy. Out-patient departments are overcrowded by patients referred chiefly by the long-list practices, and the waiting-lists of the teaching hospitals are bloated by the names of patients of whom many are not suitable for treatment at such hospitals.

Surely the answer is to make general practice respected enough to attract doctors with higher qualifications and suitable experience to take up general practice as a career—e.g., M.R.C.P., M.D., or F.R.C.S.

Hospital staffs are graded according to qualifications and experience. Why not general practitioners? In Scotland at any rate there are many satellite hospitals where such doctors could play an increasingly important role, and even where such a hospital is not readily accessible general practice should provide adequate scope.

When a vacancy occurs in a suitable practice a higher qualification plus suitable experience could be deemed an additional qualification for the vacancy. It should not be overlooked that, however much medicine advances, the benefit to the public remains meagre until the G.P. is encouraged to practise the "airt" in the home. Unless the status of the family practitioner is raised and adequate inducements are given to attract the best type of doctor to take up general practice as a career, the whole N.H.S. is doomed to failure.

The present system has converted the G.P. into a multiple signboard destined to frustrate every attempt at raising the standard and prestige of British medicine.—I am, etc.,

Fraserburgh, Aberdeen. J. MACLEOD.

Pay of Army Specialists

SIR,—Recruiting for Regular commissions in the Royal Army Medical Corps is non-existent and the shortage of specialists is acute. This will remain so until either better rates of pay are conceded or doctors find themselves unable to obtain satisfactory employment in the National Health Service. Recent events indicate that the authorities are relying on the latter event to stave off a crisis.

By advertising for civilian specialists at rates of pay higher than the Regular, and by refusing to allow the latter to resign, they evidently hope to keep going until most of the National Health specialist appointments are filled and junior specialists come cap in hand to the R.A.M.C. This will presumably happen in about eighteen months' time.

Meanwhile Regular specialists are prevented from seeking their fortune in other spheres but must serve on with an increasing sense of frustration as they see post after post for which they are qualified being filled by their civilian colleagues.

Surely the time has come for the *British Medical Journal* to refuse advertisements for civilian specialists in the Army until either higher rates of pay are conceded for the Regular or he is free to find his own level in the open market.—I am, etc.,

ARMY SPECIALIST.

The Wrong Way to Look at it

SIR,—In the *Supplement* of October 8 (p. 161), under the heading "The Wrong Way to Look at it," there are some completely unfounded suggestions. In reply to someone who has been grumbling, perhaps foolishly, against the N.H.S., the writer says: "Is it not worth while to pay something to have a healthier community at one's doors?" Yes, if it is so, but what evidence is there that the N.H.S. has made or is making such a change? It is the sort of statement that might come from a politician, not that of a man with some sort of scientific outlook such as a writer in this *Journal* should have.

One might think, if there was no evidence one way or another, that it was too soon to judge. One might have opinions, and I think I am right in saying that there is a large body of informed opinion which holds that the N.H.S. is producing, and will produce, a lower standard of medical practice, and that a lower standard of health will result. There is doubtless a contrary opinion.

The only evidence I have seen is a quotation from the *Monthly Digest of Statistics* from the Government Central Statistical Office stating that the deaths quarter by quarter in the twelve months before July 5, 1948, were lower in each quarter than in each corresponding quarter following that date, the figures for each twelve months being 461,000 and 508,600 respectively. I do not presume to comment on the significance of the figures, but they certainly do not support the writer's suggestion.

When doctors' surgeries are so crowded owing to the addition of a number of people who do not really need a doctor, it becomes impossible to make proper examinations, and cases of serious, but not obvious, illness must be more often missed. That is, those who need careful attention do not get it, for there is a limit to the capacity of the most conscientious. This, though not universal, is true of many practices.

As to the suggestion that the "daily help" would be less often absent sick—well, it seems unlikely that the N.H.S. will

be able to forestall a housemaid's knee, and, whereas in the bad old days when self-reliance was encouraged the "help" with some trivial ailment would carry on, she will now go and queue at the doctor's for a certificate and go off work with all ceremony.—I am, etc.,

E. W. SHEAF.

Guildford Surrey

National Insurance: Correction

SIR,—In the *Supplement* of October 1 (p. 149) under "Questions Answered" you reply that a wife assisting her husband as a nurse-receptionist may contribute to National Insurance in Class 2 or Class 3. I am afraid this is not correct.

The provision you quote in S.I.1948 No. 1425 refers to a partnership or similar association with the husband, and would therefore apply only to the wife who was herself a qualified practitioner. It would not apply to the wife employed by or assisting her husband as receptionist or secretary, etc., who falls into the class of non-employed persons.

A married woman who is in the non-employed persons class is under no obligation to pay National Insurance contributions and is, in fact, only entitled to do so if she has qualified by a substantial period of employment or self-employment.

Leaflet N.I.1, which sets out a married woman's rights in National Insurance, can be obtained from any local National Insurance office.—I am, etc.,

R. G. S. HOARE,
Chief Information Officer.

Ministry of National Insurance

POINTS FROM LETTERS

Discipline in Prescribing

Dr. J. E. M. BARNES (Eye, Suffolk) writes: Abuse of the National Health Service and its exorbitant cost to the nation are both points exercising the minds of all concerned very much at present. Much has been said about the "something for nothing" category of patient. I feel, however, that the profession must put its own house in order and exact some sort of discipline in prescribing before an overbearing bureaucracy exerts its stifling influence on the individual doctor's freedom of action. I happen to know that some doctors are quite casual about prescribing multiples of hundreds of vitamin and similar preparations, all without much clinical foundation . . .

Too Ill

Dr. W. M. L. HORNER (Osgathorpe, Leicester) writes: To-day I was given a message by 'phone that a patient required a visit. Not being able to manage it on my first morning round, I went first thing in the afternoon, only to be informed that the patient had gone to the dentist. Presumably the patient was not ill enough to prevent her from going to the dentist, but too ill to prevent her from going to see her doctor. Does it make sense?

Doctors and Dentists

Dr. J. McL. LEES (Walsall) writes: I have no wish to become involved in a doctor-v.-dentist quarrel. Like Mr. Ferguson Mackenzie (*Supplement*, October 8, p. 163) I think we, the medicals, provided poor opposition in the dispute with the Minister. But he could not use the Minister's tactics of figures to prove anything. I seem to remember that I had to purchase equipment.

Payment of Locums

Dr. D. G. SMITH (Cambuslang, Lanarkshire) writes: "Principal" (*Supplement*, October 8, p. 163) writes of giving partnerships away. The statement reveals a common belief which I think is wrong. It suggests that the number of patients on his list is there by some divine right and not—as far as "Principal" is concerned—as the result of a happy accident. On July 5, 1948, "Principal" sold the financial interests of his practice to the State. Whether or no it was a good business deal is irrelevant. The State actually owned his patients, but instead of paying him a salary to look after a certain number of them it allowed him to continue treating the total and, incidentally, a certain amount of money *per caput* for his trouble—not a bad arrangement provided you are a principal. It is as if in a hundred-yards sprint he was given a start of anything from fifty to ninety yards, not because he was a poor runner but because he happened to begin that part of the track—and running no less—when the race began. Is it reasonable to complain if some of the misguided individualists who began at scratch request a rearrangement of handicaps? . . .

H.M. Forces Appointments

ROYAL NAVY

Surgeon Commander C. H. Birt has been placed on the Retired List.

ROYAL ARMY MEDICAL CORPS

Short Service Commission.—Captain H. T. Chiswell, O.B.E., to be Major.

REGULAR ARMY RESERVE OF OFFICERS

ROYAL ARMY MEDICAL CORPS

Major (Honorary Lieutenant-Colonel) J. H. Walters, I.M.S. retired, to be Major.

Association Notices

TUBERCULOSIS AND DISEASES OF THE CHEST GROUP

Members of the Association interested in chest diseases are reminded that a Group has been formed of members whose work is primarily concerned with tuberculosis and diseases of the chest. Forms of application for membership of this Group may be obtained from the Secretary.

MEETING OF REGISTRARS

The National Committee of the Registrars' Association of Great Britain has petitioned the Council of the Association to form a Group of Registrars. This petition will be considered by the Council at its meeting on November 16, 1949.

The Central Consultants and Specialists Committee has agreed to the principle that registrars should be represented on its various regional committees, and that there should be a place on the Central Committee for one registrar elected from among those who are serving on the regional committees.

In order that no time may be lost in framing the constitution of a Registrar Group and in electing a Group Committee, it is proposed, pending the Council's approval of the formation of a Group, to call a mass meeting of registrars at B.M.A. House on Saturday, November 26, at 10 a.m. It is important that the meeting should be as large and representative as possible, and every practitioner holding a registrar appointment is cordially invited to attend.

CHARLES HILL,
Secretary.

Diary of Central Meetings

OCTOBER

31 Mon. Armed Forces Committee, 2 p.m.

NOVEMBER

2 Wed. Finance Committee, 2 p.m.
2 Wed. (At Lion Hotel, Shrewsbury) Welsh Committee, 2.15 p.m.
3 Thurs. Joint meeting with Chemists on Doctors' Stock Orders, 10 a.m.
3 Thurs. Central Consultants and Specialists Committee, 2 p.m.
3 Thurs. Committee on Industrial Health Services in relation to the National Health Service, 2 p.m.
4 Fri. Committee *re* Salaries of Medical Teachers, etc., 2 p.m.
8 Tues. Arrangements Committee, 2 p.m.
9 Wed Committee on the Postgraduate Education of General Practitioners, 11 a.m.
10 Thurs. General Medical Services Committee, 11 a.m.
11 Fri. Evidence oCmmittee (Royal Commission on Capital Punishment), 11.30 a.m.
16 Wed. **Council**, 10 a.m.
17 Thurs. Radiologists Group Conference, 1.30 p.m.
17 Thurs. Radiologists Group Committee (at termination of Group Conference).
25 Fri. Committee on Psychiatry and the Law, 2 p.m.

DECEMBER

22 Thurs. Occupational Health Committee, 2 p.m.

Branch and Division Meetings to be Held

BATH, BRISTOL, AND SOMERSET BRANCH.—At Physics Lecture Theatre, The Royal Fort, Bristol University, Wednesday, November 2, 8.30 p.m., annual general meeting. Presidential address: "The Forgotten Inventor."

BLACKPOOL AND FYLDE DIVISION.—Joint meeting with Blackpool and Fylde District Law Society at Clifton Hotel, Talbot Square, Blackpool, Wednesday, November 2, 7.15 p.m., reception; 7.30 p.m., dinner, followed by lecture by Mr. J. D. Cantley: "The Doctor in Litigation."

DONCASTER DIVISION.—Joint meeting with Doncaster Medical Society at Parkinson's Café, Doncaster, Tuesday, November 1, 7.45 for 8 p.m., dinner, followed by an address by Dr. W. Lomax: "Puerperal Fever."

EAST HERTS DIVISION.—At County Hospital, Hertford, Wednesday, November 2, 8.45 p.m., address by Mr. Kenneth Walker: "A Wider Approach to Genito-urinary Problems."

EAST NORFOLK DIVISION.—At Norfolk and Norwich Hospital, Wednesday, November 2, 2.30 p.m., Dr. A. V. Kelynack (Assistant Secretary, B.M.A.): "Present Policy."

GOOLE AND SELBY DIVISION.—At Lodge, Snaith, Thursday, November 3, 8.15 p.m., paper by Mr. A. J. C. Latchmore: "Recent Advances in General Surgery."

GUILDFORD DIVISION.—At Royal Surrey oCunty Hospital, Guildford, Thursday, November 3, 8.30 p.m., address by Mr. Price Thomas: "Surigcal Treatment of Carcinoma of the Lung."

MID-ESSEX DIVISION.—At St. John's Hospital, Chelmsford, Sunday, November 6, 10 a.m., Dr. I. Gordon: "Treatment of Heart Failure."

PADDINGTON DIVISION.—At Wright-Fleming Institute, St. Mary's Hospital, Praed Street, London, W., Thursday, November 3, 8.30 p.m., lecture-demonstration by Professor R. Cruickshank: "The Laboratory's Part in the Diagnosis and Treatment of Disease." Members of neighbouring Divisions are invited.

ROCHDALE DIVISION.—At Providence School, High Street, Rochdale, Friday, October 28, 8.30 p.m., clinical meeting. Dr. L. D. Walker, Medical Director of No. 4 Mass Radiography Unit, will demonstrate the working of the Unit.

SWANSEA DIVISION.—At Swansea General Hospital, Thur: November 3, 7.30 p.m., clinical meeting.

WEST HERTS DIVISION.—At Peace Memorial Hospital, Rickmansworth Road, Friday, November 4, 8.30 p.m., joint meeting with West Herts and Watford Medical Society. Dr. Robert Forbes: "Legal Hazards in Medical Practice."

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar

Non-County Borough Councils.—Dartford, Wallsend.

Urban District Councils.—Denton, Drovlsden, Houghton-le-Spring, Huyton-with-Roby, Redditch (restricted to new appointments), Tyldesley.

BRITISH MEDICAL JOURNAL

LIVER DAMAGE PRODUCED BY FEEDING ALCOHOL OR SUGAR AND ITS PREVENTION BY CHOLINE*

BY

C. H. BEST, M.D., F.R.S. W. STANLEY HARTROFT, M.D.
C. C. LUCAS, Ph.D. AND JESSIE H. RIDOUT, Ph.D.

(From the Banting and Best Department of Medical Research, University of Toronto)

[WITH PHOTOGRAVURE PLATE]

One of the first suggestions that over-indulgence in alcoholic beverages may damage the liver was made by Thomas Addison, physician to Guy's Hospital, London (Addison, 1836). He wrote: "With respect to the causes of this fatty degeneration of the liver, very little, or absolutely nothing, is known. In most of the cases which I have met with, there has been either positive or strong presumptive evidence that the individual had indulged in spirit-drinking; and indeed the most exquisite case I ever saw in a young subject occurred in a female who had for some time subsisted almost exclusively on ardent spirits. On the other hand, the extreme frequency of the degeneration in France, where the people are but little given to such indulgence, throws considerable doubt upon such an origin of the complaint."

A few years later Rokitansky (1849), pathologist to the Imperial Royal General Hospital in Vienna, reached a similar conclusion concerning the responsibility of alcohol for at least one type of fatty liver. Rokitansky noted the frequent occurrence of cirrhosis of the liver in drunkards. He was possibly the first to suggest that cirrhosis follows fatty changes in the liver.

The earliest references to experimental studies of the effects of alcohol were concerned with its effect on the brain (Dahlström, mentioned by Magnus Huss, 1852; Duchek, 1853). Kremiansky (1868), in the course of similar investigations, noted that one of four dogs receiving increasing doses of alcohol up to 6 oz. (170 ml.) daily for three months developed fatty changes of the liver and heart and a catarrhal condition of the kidneys. Ruge (1870), however, seems to have been the first to show clearly that an accumulation of fat occurs in the livers of dogs given increasing daily doses of alcohol by stomach-tube. He noted incidentally that the nature of the diet influenced the amount of fat found in the liver.

Moon (1934), in his comprehensive and critical review of the experimental work on alcoholic cirrhosis, concluded that none of the experimental procedures had been successful in producing cirrhosis in animals, other than rabbits, by alcohol alone. He pointed out that many of the so-called "positive" results with rabbits must be discounted owing to the presence of intercurrent liver infections (coccidiosis, etc.) or to a chronic periportal inflammation which is common among adult untreated rabbits. Moon concluded: "Without minimizing the contributory or predisposing influence which alcohol may exert, it must be concluded that experimental evidence has not substantiated the belief that alcohol is a direct cause of cirrhosis."

Experimental evidence that long-continued presence of abnormal amounts of fat in the liver does give rise to cirrhosis was supplied by Chaikoff, Connor, and Biskind (1938) using depancreatized dogs which had been maintained with insulin for periods up to five years. Production of cirrhosis in normal dogs by feeding alcohol to animals in which a fatty liver had previously been established by dietary means was reported by Connor and Chaikoff (1938), but the relationship of the alcohol to the cirrhosis became questionable when Chaikoff and Connor (1940) produced cirrhosis in normal dogs by dietary means alone (high fat and low protein). A series of papers from the National Institute of Health, Bethesda, Maryland, reported that the consumption of alcohol by rats increased the severity of dietary cirrhosis and that supplements of choline chloride or of methionine (or an increase in the dietary casein) prevented the development of cirrhosis and were beneficial in its treatment (Daft, Sebrell, and Lillie, 1941; Lillie, Daft, and Sebrell, 1941; Lowry, Daft, Sebrell, Ashburn, and Lillie, 1941; Lowry, Ashburn, Daft, and Sebrell, 1942; Lillie, Ashburn, Sebrell, Daft, and Lowry, 1942).

More recently, however, Ashworth (1947) concluded that alcohol exerts a toxic effect even when the diet is adequate. Rats on high-casein diets and others on low-casein diets were given 1.5 ml. of 25% alcohol per 100 g. body weight by stomach-tube daily for two months, and 10% alcohol was supplied in place of drinking-water: control groups without alcohol were "pair-fed" the same basal diets. Since all the rats lost weight, whether alcohol was present or not, it is questionable whether the basal diets were adequate. Interpretation of the data is therefore difficult (see "Discussion").

Although Ashworth (1947) pair-fed his rats, the calorie intake of those consuming alcohol was considerably in excess of those drinking water. To determine what effect calorie imbalance might have upon the results, we have performed experiments in which, for the first time in a

*A very brief account of this work was presented at the Detroit Meeting of the American Physiological Society, 1949.

study of the effects of alcohol, isocaloric pair-feeding has been used. Groups of rats not receiving alcohol were isocalorically pair-fed with those ingesting alcohol. The extra calories (equivalent to those supplied by the alcohol) were provided as finely powdered sucrose.

The effects of various lipotropic supplements added to the diets of the rats consuming alcohol were studied. The pathological changes in the liver produced in these experiments are attributed to an imbalance of calories and vitamins, particularly to an induced inadequacy of lipotropic factors consequent upon the increased calorie intake. Adequate amounts of choline chloride, methionine, or casein always protected the liver. Under these particular experimental conditions there is no more evidence of a toxic effect of pure ethyl alcohol upon the liver cells than there is of a poisonous action of an amount of sucrose which supplies the same calorie intake. In fact, there is no suggestion that either alcohol or sucrose exerts a direct hepatotoxic effect. The fatty and fibrotic changes are due to a deficiency of the lipotropic factors.

Experimental

A total of 188 male rats (150 to 200 g.) were divided among 12 groups unequal in numbers but with comparable weight distribution (see Table I). The animals were housed

TABLE I.—*Liver Lipids and Fibrosis*

Supplement	Diet Alone *ad lib.*	Diet *ad lib.* + Alcohol	Diet Alone (Pair-fed)	Diet Pair-fed + Sugar (Isocaloric)
None	**0** (10) 10% 0/6	**2** (20) 18% 7/15	**3** (32) 10% 2/28	**4** (12) 26% 7/9

Average daily food consumption (without alcohol), 14 to 15 g.
Average daily food consumption (with alcohol), 11 g.
Alcohol supplied 18% total calories in Groups 2, 5, 8, and 10.
Group numbers in bold face type and original number of rats per group in parentheses. Average total liver lipids as percentage of fresh liver weight is shown below group number; number of livers showing fibrosis is given as numerator of a fraction in which denominator is the number of livers carefully examined after rats had eaten diets for 6 months.

in individual all-metal cages provided with a false bottom of coarse wire screen. A 15% (by volume) aqueous solution of purified ethyl alcohol was given in place of drinking-water to four groups of rats throughout the whole experimental period, which lasted 177 days. These groups (2, 5, 8, and 10) were offered their respective diets and the alcoholic solution *ad libitum*, and the amounts of each consumed were recorded daily. Four other groups of rats (4, 6, 7, and 11) started four days later were fed the same amount and kind of diet consumed by Groups 2, 5, 8, and 10, respectively. An attempt to achieve calorie equivalence was made by adding enough powdered sucrose to each of the former diets to supply the calories provided by the alcohol consumed by the corresponding group. These groups of rats and the remaining ones were given tap-water *ad libitum*. To assess the effects of the extra calories provided by the alcohol (or sucrose supplement) it is necessary to know the effects of the amount of basal diet consumed by the rats of Groups 2 and 4. The rats of Group 3 (started four days later than those of Group 2) were therefore "group pair-fed" on a diet-weight basis with those of Group 2. Only 12 rats were available for this group when the main experiment was started (June 24, 1948); 20 rats (referred to as Group 3A) were started one month later under identical dietary conditions. The rats of Group 0 were included to observe the effects of the basal diet alone when offered *ad libitum*, and those of Groups 1 and 9 were used to study the effects of the lipotropic supplements (choline and protein, respectively) when added to the basal diet and fed *ad libitum*. Further experimental conditions will be described in detail in the following paragraphs.

The Diet

A basal ration was desired which would be as nearly adequate as possible in all its dietary components except the lipotropic factors. However, it was considered inadvisable to permit an excessive accumulation of liver fat, since any effect attributable to alcohol alone would be difficult to assess if superimposed on a liver made excessively fatty by the basal diet. The small amount of choline chloride (0.05%) added to the basal ration was determined by preliminary experiments to be just sufficient to maintain the total liver lipids at about 10%, which was arbitrarily considered to be a satisfactory basal level for these particular studies.

The basal diet had the following composition, in percentages: casein 10, gelatin 5, zein 3, cystine 0.3, salts (Beveridge and Lucas, 1945) 5, celluflour 2, sucrose 41.7, starch 10, dextrin 10, beef fat 10, corn oil 2, "vitamin powder" 1, cod-liver-oil concentrate* 0.015, α-tocopherol acetate 0.01, choline chloride 0.05. The "vitamin powder" contained thiamin hydrochloride 0.5 g., riboflavin 0.25 g., pyridoxin hydrochloride 0.2 g., calcium pantothenate 1 g., nicotinic acid 1 g., folic acid 0.05 g., 2-methyl-1-4-naphthoquinone 0.1 g., para-amino benzoic acid 10 g., and inositol 50 g., made up with finely powdered sucrose to 1,000 g. Rats consuming 10 g. of diet daily received 50 μg. of thiamin hydrochloride and corresponding amounts of the other vitamins.

The methionine content of the diet was estimated to be 420 mg. and the cystine content (with the supplement) was 380 mg. per 100 g. Using calorie values per g. of 4 for protein, 4 for carbohydrate, and 9.3 for fat, the energy content of the basal diet was calculated to be 4.35 calories per g., of which 58% was contributed by the carbohydrate. The diets were freshly prepared at least once a week. The major dry ingredients for 5 kg. of diet were thoroughly mixed in a Hobart food-mixer, and a small portion (about 500 g.) was spread in a thin layer on a large tray. The minor ingredients (vitamin powder, cystine, or methionine) were ground individually in a mortar with small portions of the dry mixture, and this was then sifted (40-mesh sieve) over the surface of the material in the tray. The choline chloride was ground separately until uniform with about 10 g. of the dry mixture, and then more of the dry mixture was added to the mortar until about 40 g. was present. This mixture was sprinkled over the surface of the material in the tray. The cod-liver-oil concentrate and α-tocopherol acetate were dissolved in petroleum ether and sprayed over the same mixture. The contents of the tray were mixed by hand and then returned to the Hobart mixer and blended thoroughly. The beef fat was melted and brought to a temperature of 130° to 140° C., the corn oil was added, and the hot fat was poured all at once into the mixer and blended until uniform. The diets were kept in tightly closed tinned cans in a refrigerator at about 4° C. until required for use.

Alcoholic beverages and commercial ethyl alcohol contain compounds other than ethanol. To what extent the other components (in some cases unknown) contribute to the effects of alcohol upon the liver cannot be stated. Since

*This concentrate (Ayerst, McKenna, and Harrison, Ltd., Montreal, Canada) contained 200,000 i.u. vitamin A and 50,000 i.u. vitamin D per g.

the effects of ingesting alcohol may be due to the contaminants, the ethanol, or the ratio of dietary calories to the adequacy of other nutriments, it was considered important to eliminate the contaminants as completely as possible. Freshly prepared silver oxide (about 10 g. per litre) was added to so-called pure 95% ethyl alcohol. The mixture, shaken frequently, was left at room temperature for at least 24 hours. The alcohol was then decanted, made just alkaline with sodium hydroxide, and distilled through a packed fractionating column running at a reflux ratio of about 10 to 1. The first 20% of distillate was rejected, about 50% was collected, and the remainder was discarded. A 15% (by volume) aqueous solution of this material replaced the drinking-water of four groups (2, 5, 8, and 10) of rats. Fresh liquid was supplied twice a week. It was dispensed to the rats from 6-oz. (170-ml.) medicine bottles through a short piece of curved glass tubing with a tip slightly constricted in the flame so that liquid would not run out unless the rat lapped it. Sudden movements of the cage door were avoided to minimize leakage, since it was found that jarring the bottle permitted loss of a few drops of liquid. Losses due to evaporation were shown to be negligible (less than 0.3 ml. per day). Whenever, for any reason, abnormally large amounts of liquid seemed to have been consumed, leakage was suspected; the average consumption of alcohol during the previous week was then used to calculate the calories thus obtained by the rat.

Technique of Feeding

The animals in Groups 2 and 4 were paid-fed on an isocaloric basis. The technique used in this isocaloric pair-feeding (which applies also to Groups 5 and 6, 8 and 7, 10 and 11) will be described in detail. The rats of Group 2 consumed the basal diet *ad libitum*, with 15% alcohol to drink; the total calorie intake was determined from the average consumption of food and alcohol over three-day periods. The rats in Group 4 (started four days later) were offered the basal diet in an amount equal to the average value noted for those in Group 2, and enough finely powdered sucrose was added to this food (with thorough mixing) to supply the calories contained in the average amount of alcohol consumed by the rats of Group 2. The calculation of the amount of sucrose required was made on a somewhat arbitrary basis. Mitchell and Curzon (1940), in a review dealing with the food value of ethyl alcohol, stated that "for reasons at present unknown the energy of alcohol is not as well utilized in metabolism as is the energy of glucose." Mitchell (1935) estimated that the energy of alcohol is only about three-fourths as available for physiological purposes as that of sucrose. He stated that its growth-promoting power is definitely less than that produced by a sucrose supplement. In the absence of more specific information we assumed that calories from alcohol were only three-quarters as effective in causing gains in weight as were those of the sucrose supplements. Since 1 ml. of absolute ethyl alcohol weighs 0.79 g. and the calorie value is given as 7.1 cal. per g., then 1 ml. contains 5.6 cal., or 1 ml. of 95% alcohol corresponds to 5.3 cal. One ml. of a 15% by volume dilution of the 95% alcohol would supply 0.8 cal.: finally, if only three-quarters of this is available for promoting gains in weight, then 1 ml. is equivalent to 0.6 cal., or approximately to 0.15 g. of sucrose.

The rats were maintained on these dietary regimens for 177 days. Pairs of rats chosen at random from Groups 0, 2, 4, 5, 7, 8, 9, and 10 were killed at three weeks to determine to what extent deposition of liver lipids was taking place; again after 12 weeks pairs of rats from Groups 2 and 3 were sacrificed. All rats were anaesthetized with sodium amytal (90 mg. per kg. body weight, intraperitoneally). The animals were exsanguinated and the livers were removed and weighed immediately. Portions of right and left lobes were taken for histological examination; the remainder was re-weighed and the total liver lipids were determined (Best, Lucas, Patterson, and Ridout, 1946). Blocks of liver, kidney, and certain other tissues were fixed in Heidenhain's SUSA mixture for 24 to 48 hours. Paraffin sections were stained with haematoxylin and eosin, and, to demonstrate connective tissue, with azocarmine, aniline blue, and orange G. The degree of fatty vacuolation of the liver cells was recorded as 0, +, + +, + + +, or + + + +. These histological data were in agreement with the results of chemical determinations, and therefore only the latter are included in the Table. Numerous sections from each liver were examined carefully for signs of fibrous-tissue proliferation.

Results

No abnormalities were detected on gross, microscopical, or chemical examination of the livers of any of the animals receiving the diets containing the lipotropic supplements, whether or not alcohol (or extra sugar, isocaloric with the alcohol) had been consumed. The rats maintained on the basal diet alone (Group 0) grew well and (with the exception of one rat which showed some pancreatic disease) the total liver lipids ranged from 7.7% to 12.8%, with an average of 9.3%, and no liver fibrosis was observed. The average daily food consumption of the rats allowed to eat this diet *ad libitum* was reasonably constant at about 14 to 15 g., as was that of the other rats not consuming alcohol and eating *ad libitum* (Groups 1 and 9). All the rats consuming alcohol (Groups 2, 5, 8, and 10) ate less—only about 11 g. daily. The rats in the pair-fed groups (3, 4, 6, 7, and 11) were therefore offered 11 g. of the corresponding diets daily. The rats of Group 3 gained less weight because of this restricted food intake, but their livers showed essentially the same chemical and histological picture as those of the rats of Group 0.

The rats consuming alcohol without adequate lipotropic factors in the diet (Group 2) developed fatty livers with an average total lipid content (20%) about double that of the rats consuming the same amount of diet without alcohol (Group 3). One-half of the surviving rats drinking alcohol and eating the basal diet (Group 2) exhibited hepatic fibrosis, while in those without alcohol (Group 3) fibrosis could be detected in only two out of 28 survivors, and in one of these the fibrosis was minimal. The rats fed sugar isocalorically—i.e., those of Group 4—had on the average more fat (26%) in their livers and a somewhat higher incidence of fibrosis (7 out of 9 survivors) than those receiving the alcohol (Group 2). However, in none of the livers of either Group 2 or Group 4 had the fibrosis advanced sufficiently to be considered frank cirrhosis. The greater production of fibrosis in the rats of Group 4 (sucrose) than in those of Group 2 (alcohol) probably may be explained by our failure to achieve an exact equivalence in calories between the rats of these two groups. Some evidence for this is apparent in Chart I, in which it will be noted that the average final weight of the rats receiving the sugar supplement exceeded by about 16 g. that of the rats consuming alcohol. This is a rather small discrepancy in weight at the end of a test period of six months, but the difference it represents in calorie intake may be sufficient to account for the slightly greater liver damage. Chart II indicates a more successful attempt at pair-feeding in the [illegible]rmation receiving choline. The curves require no further [illegible]nt except that the dips seen in all of

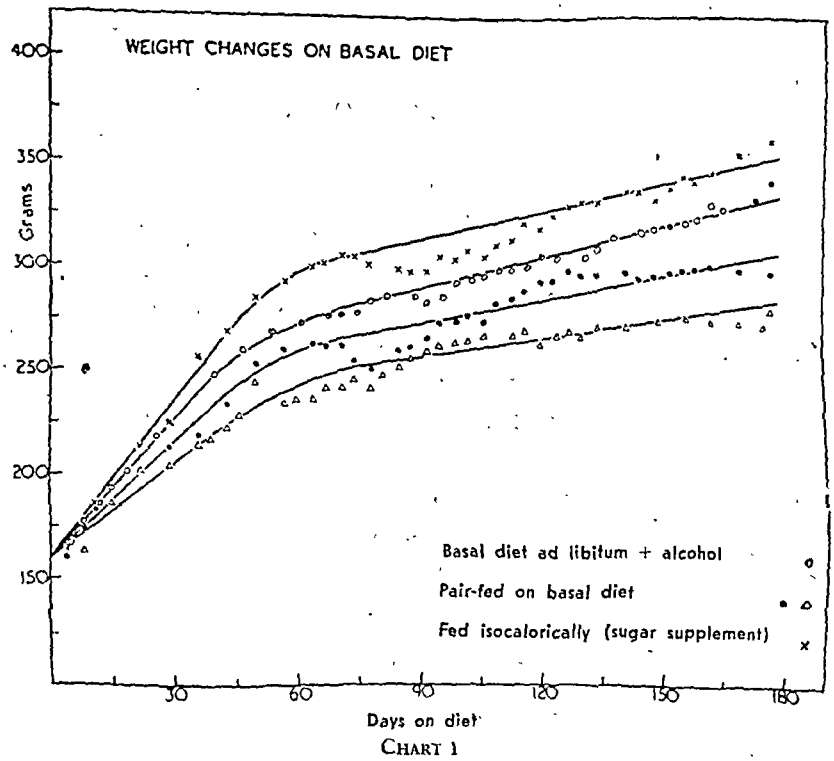

CHART I

them at about 80 to 90 days are related to a period of exceedingly hot weather, during which the air-conditioning equipment failed to function properly. Since the growth curves of the animals given supplements of methionine or casein (Groups 7, 8, 10, and 11) are essentially the same as those in Chart II, they will not be presented. The rats of Group 0 (basal diet *ad libitum*) grew most rapidly, those of Groups 1 and 9 only slightly less well. The rats of Group 0 consuming 14.9 g. of food per day (65 calories) gained on the average 262 g. Those of Group 3 consuming 11.2 g. (49 calories) of the same diet gained only 137 g. Rats of Group 2 eating essentially the same amount (11.4 g.) of diet but obtaining also 11 calories from alcohol—i.e., a total of 61 calories per day, 18% of which came from alcohol—gained 182 g. Rats of Group 4 ate 11.2 g. of diet daily and were given an average sugar supplement of 2.7 g. (total calories 60, of which 18% was supplied by the sucrose supplement); they gained 198 g. Thus rats of Group 0 eating 3.5 g. more food per day than those of Group 2

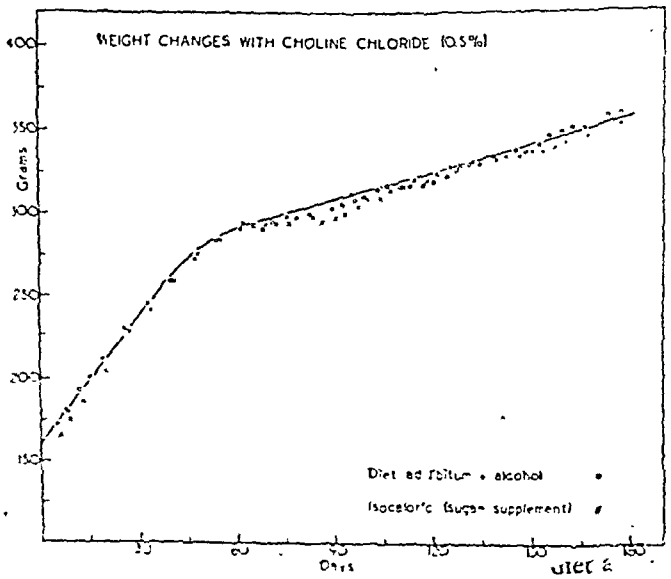

CHART II

gained 80 g. more than did the latter; in spite of the calories obtained by the rats of Group 2 from the alcohol, they were still getting from 4 to 5 calories per day less than those eating the basal diet *ad libitum*. The stunting of growth frequently attributed to the toxic action of alcohol is in these experiments due mainly to decreased food intake, unless one is willing to make the highly improbable assumption that sucrose exerts the same toxic effect as alcohol.

Fig. 1 (Plate) shows the typical histological picture seen in fatty livers (without fibrosis) of the rats consuming the basal diet with alcohol; Fig. 2 shows the same for rats on the basal diet with sugar fed isocalorically; Figs. 3 and 4 illustrate the distribution of fibrous tissue (when present) in the livers of the two groups. After careful study of many sections from all the livers these two examples were selected as representative of the two groups. The similarity in fat deposition and in the nature and extent of the fibrosis in the livers of the two groups is remarkable. Equally striking is the absence of abnormalities in the livers of the animals receiving adequate lipotropic supplements, as has already been mentioned.

Discussion

Clinicians in North America and Europe have tended for many years to associate chronic alcoholism and cirrhosis. In parts of Asia and Africa, however, cirrhosis is common although alcoholism is rare. In these regions it has been noted that cirrhosis occurs most often in persons subsisting on deficient diets. Thus a consideration of the incidence of cirrhosis throughout the world reveals a correlation with malnutrition. This situation may be obscured in some areas by a high incidence of cirrhotic changes following various forms of hepatitis. Within recent years it has been recognized that the chronic alcoholic, like other malnourished individuals, often shows signs of various dietary deficiencies: the intakes of good proteins and of vitamins of the B complex are generally low.

We are not considering in this paper the effects of alcohol on tissues other than the liver. Whether or not alcoholic beverages *per se* directly injure the liver has been a subject of controversy. Even if it could be proved that these beverages do exert a toxic effect upon the liver it would still have to be shown whether the effects were due to pure ethanol, to associated toxic contaminants, to a general malnutrition, or to one or more specific dietary deficiencies.

The present series of experiments does not supply any information whatever on the possible effects of toxic agents which may occur as natural contaminants of alcoholic beverages available in commerce. However, fatty infiltration and consequent fibrosis, which closely resemble the lesions in the chronic alcoholic, have been seen in these experimental animals consuming a purified alcohol. One is therefore tempted to assume that the hypothetical toxic contaminants may be of minor importance in causing the liver lesions seen in the human alcoholic.

The above experiments show that a carefully purified sample of ethanol can cause an excessive accumulation of fat in the liver and subsequent development of fibrosis when the diet lacks adequate amounts of the lipotropic factors. Since, however, pure sugar caused lesions of a similar nature and extent, and since these, as well as those due to alcohol, were entirely prevented by dietary choline or its

Problems connected with the proposal to supplement alcoholic beverages and saccharine aerated water ("soft drinks") with choline or its precursors are mentioned.

Our findings are, of course, not necessarily applicable to alcoholism in human subjects. If they should prove to be so, it is increasingly obvious that individuals who habitually consume large amounts of alcohol or sugar lack adequate amounts of the lipotropic agents as well as of other dietary essentials.

The classical hepatic lesions (fatty changes and fibrosis) associated with alcoholism in human subjects, the first descriptions of which are mentioned in our introduction, may prove to be due specifically to a lack of the lipotropic agents.

This work has been supported by the Nutrition Foundation of New York and the Banting Research Foundation, Toronto. We are indebted to our colleague Dr. Jean Patterson for her invaluable help. The photomicrographs were prepared by one of the authors (W.S.H.) with the technical assistance of Mrs. K. M. Robertson.

THE PRE-ERYTHROCYTIC STAGE OF PLASMODIUM FALCIPARUM

A PRELIMINARY NOTE

BY

H. E. SHORTT, C.I.E., M.D., D.Sc., D.T.M.&H.
N. HAMILTON FAIRLEY, C.B.E., F.R.S.
G. COVELL, C.I.E., M.D., D.T.M.&H., D.P.H.
P. G. SHUTE

AND

P. C. C. GARNHAM, M.D., D.P.H.

The demonstration of a pre-erythrocytic cycle in mammalian malaria as it exists in the monkey malaria parasite, *Plasmodium cynomolgi* (Shortt and Garnham, 1948), led to the deduction that a similar cycle would be found in the case of human malaria caused by the parasite *P. vivax*. This followed from the close similarity of the two parasites, and the assumption was quickly proved experimentally by the discovery of the pre-erythrocytic cycle in a human volunteer (Shortt, Garnham, Covell, and Shute, 1948). In both cases the pre-erythrocytic cycle was shown to take place in the parenchyma cells of the liver.

It was subsequently demonstrated that this cycle persisted in the liver after the establishment of the infection in the peripheral blood and that it was the probable cause of relapses in benign tertian malaria, since it could exist in the absence of the erythrocytic cycle.

The work of Fairley (1945, 1947) showed conclusively that in both vivax and falciparum malaria there was a cryptic phase in infections caused by mosquito bites during which pre-erythrocytic development must have been proceeding in some situation other than the blood stream. No other conclusion could be drawn from the results of his experiments, and he established the approximate duration of this cryptic phase as eight days in the case of vivax malaria and six days in the case of falciparum malaria.

As already stated above, the truth of this assumption had been established in the case of vivax malaria, but similar proof was still lacking in the case of falciparum malaria, and it was to obtain this that the experiment which is the subject of this paper was carried out.

Unlike the case in vivax malaria, we were unable to argue from monkey to man, since no suitable monkey parasite closely similar to *P. falciparum* was available for study, and a human experiment was necessary without any preliminary comparative work.

The fact that *P. falciparum* shows considerable differences in its morphology and life cycle from *P. vivax* at least raised the possibility that there might be certain differences in the nature of the cryptic stage as compared with those of *P. vivax* and *P. cynomolgi*, as well as in the site in the body where it occurred. It seemed probable, also, if we accept the persisting exo-erythrocytic cycle as the source of relapses in vivax malaria, that, although there would be a pre-erythrocytic cycle in falciparum malaria, it would be short-lived and end with establishment of the erythrocytic infection. This is a natural deduction from the well-known fact, so conclusively proved by Fairley's experiments alluded to above, that complete eradication of the erythrocytic infection in falciparum malaria ends the disease and relapses do not occur. This made the problem of choosing the correct day for the biopsy on the volunteer of great importance, as will be seen when the details of the experiment are described.

Description of Experiment

Anopheline mosquitoes of the species *A. maculipennis atroparvus* and *A. quadrimaculatus* were infected by feeding on two occasions on a subject carrying in his blood large numbers of gametocytes of a Rumanian strain of *P. falciparum*. These were maintained on blood meals for fourteen days, and mosquitoes were dissected and examined daily to follow the progress of the infection. These dissections revealed an infection rate of 93%. After ten days the dissections showed that the salivary glands had been invaded, and it was considered that four days afterwards would be the optimum time to feed them on the volunteer.

This operation was carried out on three days as follows, a total of 770 bites by the mosquitoes being recorded.

On October 10, 1949, 350 mosquitoes fed; on October 11, 95 fed, these being the mosquitoes that had failed to feed on the first day. On October 12, 325 fed: the majority of these were the mosquitoes of the first day of feeding having a second blood meal on the volunteer.

The dissections referred to had shown that 93% of the mosquitoes were infected and that the infections in the salivary glands were extremely heavy, so that the dosage of sporozoites injected by the 770 bites must have been enormous.

After a full consideration of all the factors involved, and influenced chiefly by the duration of the incubation period

in falciparum malaria after infection by mosquitoes as exemplified in Fairley's work already alluded to, we decided to perform a biopsy and remove a piece of liver from the volunteer by open operation 140 hours after the initial feed of the mosquitoes. This implied the assumption, later proved to be correct, that the exo-erythrocytic stages would be found in the liver as in the cases of *P. cynomolgi* and *P. vivax*. As the mosquitoes had fed on three successive days, it will be evident that the hypothetical pre-erythrocytic forms at the time of the biopsy would be at three different stages of development separated by approximately 24-hour intervals. At the operation, performed by Mr. C. Naunton Morgan, a wedge-shaped piece of liver measuring about 1 in. by $\frac{1}{4}$ in. by $\frac{1}{2}$ in. (2.5 by 1.9 by 1.25 cm.) was removed. This was divided into pieces of appropriate size and fixed in Carnoy's fluid. Sections cut from this material were stained by the colophonium–Giemsa method (Shortt and Cooper, 1948).

Microscopical Examination of the Sections

In the liver sections were found pre-erythrocytic schizogony forms of *P. falciparum* very similar to those of *P. cynomolgi* and *P. vivax* but with differences noted below.

As expected, three stages have been found. The most advanced forms probably correspond to those initiated on the first day of infection by the mosquitoes, and were approximately 140 hours old; the second correspond to the second day of infection, and were approximately 116 hours old; while the least-advanced correspond to the third day of infection, and were approximately 92 hours old.

It must not be supposed that the examples of these three stages were all sharply differentiated in their degree of development, since there were two infection periods, separated by several hours, on each of the days in which the infecting mosquitoes fed, and this was responsible for some grading in the degree of development of the schizonts without materially affecting the differentiation of the schizonts found in the three stages corresponding to the three "infection" days. All appeared to be contained in the parenchyma cells of the liver.

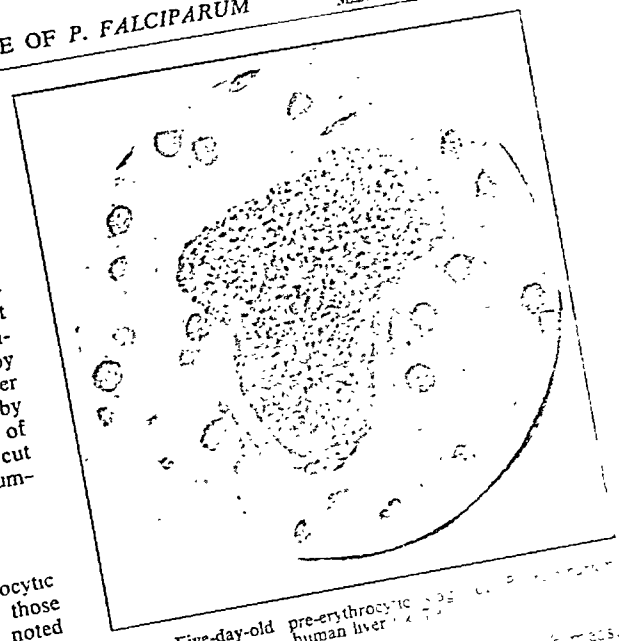

FIG. 2.—Five-day-old pre-erythrocytic [illegible] human liver [illegible]

Forms 140 Hours Old.—In these forms [illegible] up to 60 μ or more in length [illegible] merozoites were already formed [illegible] rupture or already in process of [illegible] merozoites into the surrounding [illegible] of the schizonts stained a blue or [illegible] the nuclei or chromatin masses [illegible] shape of the schizonts varied [illegible] some cases, however, an apparent [illegible] the source of which seems obscure. The [illegible] very small, measuring about [illegible] numerous.

Forms 116 Hours Old.—Until [illegible] detailed examination of our material has been [illegible]

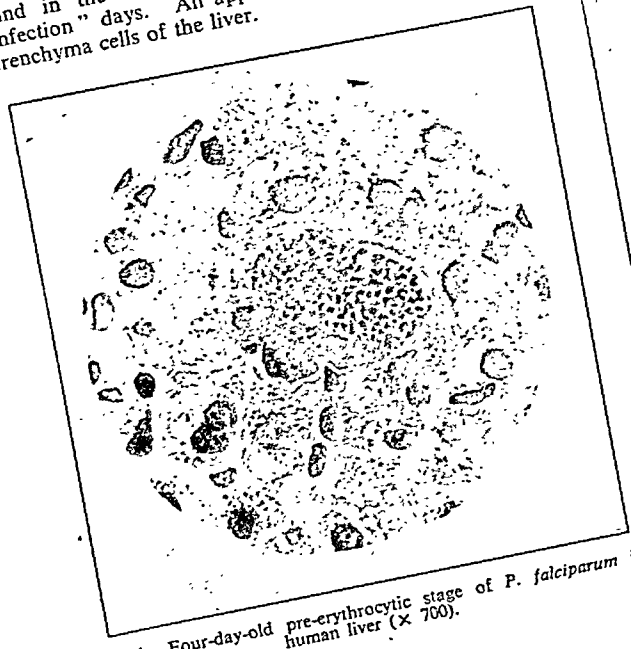

FIG. 1.—Four-day-old pre-erythrocytic stage of *P. falciparum* in human liver (× 700).

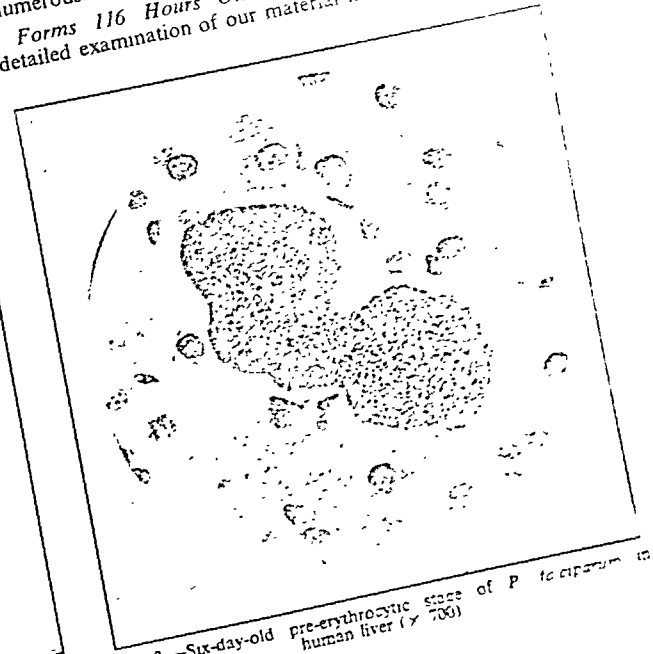

FIG. 3.—Six-day-old pre-erythrocytic stage of *P. falciparum* in human liver (× 700).

not be possible accurately to date the forms younger than the fully developed schizonts ready to rupture. In all the younger forms the nuclei were larger but much less numerous and the cytoplasm more abundant, the staining reactions remaining the same. The schizonts, which were ovoid or bluntly lobose in shape, were not quite so large as in the previous stage, but a large example would measure about 50 μ by 36 μ in the long and short diameters. This would probably represent a late fifth-day form.

Forms 92 Hours Old.—The schizonts were considerably smaller than the previous form, measuring about 31 μ by 26 μ in their longer and shorter diameters. They tended to be ovoid in shape, but lobose forms or forms constricted in the middle were already appearing. The blue cytoplasm was coarsely granular and the nuclei were much less numerous than in the previous stage. As in the cases of *P. cynomolgi* and *P. vivax*, there was no cellular reaction to the presence of the parasitic bodies in the liver tissue in any of the three stages described.

Comment

In comparing the various stages described with those found in *P. cynomolgi* and *P. vivax* it will be evident that the pre-erythrocytic forms of all three species are closely similar. Points of difference are the larger size of the mature schizont of *P. falciparum*, the smaller size of the merozoites, and the much greater number of these in the schizonts. The full maturity of the schizonts in less than six days proves that schizogony in the pre-erythrocytic forms of *P. falciparum* proceeds much more rapidly than in either *P. cynomolgi* or *P. vivax*.

The general impression gained, however, is that the three species must be considered closely related and that the genus *Plasmodium*, as exemplified in these three species whose essentially complete life cycles are now known, is a compactly knit entity the members of which conform closely to the generic pattern.

Summary

For the first time the existence of a pre-erythrocytic stage in the life cycle of *P. falciparum* has been demonstrated and the forms at three stages of development are briefly described.

We express our great indebtedness to many helpers who have assisted at various stages in the carrying out of this successful experiment. Our special thanks are due to Mr. C. Naunton Morgan, who performed the open operation on the liver with remarkable skill and celerity, to Dr. C. Langton Hewer, who gave up valuable time to administer the anaesthetic to the [illegible] and to the staff of the Hospital for Tropical Diseases [illegible] assistance and care throughout the experiment. Dr. W. D. Scott, physician superintendent of Horton Hospital, has earned our gratitude by granting the most ample facilities for the artificial infection of the mosquitoes at Epsom and their subsequent use on the human volunteer. Mr. W. Cooper, chief technician, Miss Maryon, and Mrs. P. Lee gave invaluable and skilled assistance and spared neither time nor trouble in many laborious technical operations. The one indispensable actor in the experiment was the human volunteer, Mr. C. H. Howard, who not only offered himself, but on his own initiative, offered himself for [illegible] and thereby helped greatly to advance scientific knowledge on an important aspect of malariology.

REHABILITATION AND RESETTLEMENT OF THE TUBERCULOUS*

BY

FREDERICK HEAF, M.A., M.D., F.R.C.P.

Adviser in Tuberculosis to the Ministry of Health; Senior Medical Officer, London County Council

In all matters concerning the resettlement and rehabilitation of the tuberculous three factors are of paramount importance. The first is that it is impossible to be sure that a tuberculous person has completely recovered from his disability; the second is that there are no means of assessing a tuberculous person's capacity for work except by trial and error; and the third is that when the disease is active it is usually infectious. These three factors differentiate the problem of other disabled persons from that of the tuberculous and make it necessary to have special schemes to meet the requirements of the latter group. I propose to examine in more detail the three factors with special reference to resettlement and rehabilitation.

1. Uncertainty about Recovery

It is not easy to find reliable statistics on the relapse rate of those who have been treated in sanatoria. There are many reports on the post-sanatorium mortality rate which are helpful, but these do not indicate the amount of chronic invalidism amongst the tuberculous population. Here are some conclusions taken from studies of after-histories of patients.

Bashford and Scott (1936) in their report on the health of 3,755 Post Office workers state: "Of those who incur pulmonary tuberculosis not more than 50% are able to return to work even after prolonged periods of treatment, and of those who return there has been a further wastage of about 48% as a result of recurrent pulmonary tuberculosis, or other form of ill-health, by the end of ten years, the heaviest wastage having occurred in the first six years."

Tattersall (1949), in a five-year follow-up of sputum-positive cases, found that 10% of the "recovered" cases deteriorated after an average period of six years as "recovered." He suggests that a patient whose working capacity is reduced by phthisis is not always a short-term social liability, and that it is doubtful if there is any justification in discharging from supervision any tuberculous person who has had a positive sputum.

Such information, although emphasizing the need for special measures for rehabilitating the tuberculous, is not particularly encouraging, and it would be as well at this point to inquire why the tuberculous relapse and die. A satisfactory answer to this query cannot be given; all that can be said is that certain conditions predispose to activity of the disease. Which of these conditions is the most important varies from individual to individual. Undernutrition, overstrain, anxiety, acute respiratory infections, insufficient rest, and certain occupational conditions are factors that influence the state of the lesion, and the facts may be summarized in a brief but vague way by saying that anything that lowers the resistance of the body to infection will increase the possibility of a breakdown from tuberculosis. This is really begging the question, as resistance is a term which cannot be defined. The inability of the body to rid itself of the tubercle bacillus is well known, and he would be a bold man who said that in any arrested

*Read in the Section of Occupational Health at the Annual Meeting of the British Medical Association, Harrogate, 1949.

case of tuberculosis no live tubercle bacilli were to be found in the body. Careful examination of even calcified lesions often reveals the presence of living bacilli, and so long as they are there it is possible for activity to develop.

The experience of two great wars and studies of the mortality figures of tuberculosis in relation to environment have shown that when the standard of living falls tuberculosis rises. Thus the first principle in the resettlement of the tuberculous is that the standard of living of tuberculous persons must be kept high. The mortality rates during the last ten years in countries like Denmark, Sweden, and the U.S.A., where the tuberculosis death rates actually fell during the war years, show clearly the relationship of the national standard of nutrition to tuberculosis mortality rates, and recent figures published in *Tubercle* (1948) reveal a close connexion between protein intake and tuberculosis mortality. It is therefore essential in any tuberculosis resettlement scheme to be sure that a good standard of nutrition is maintained. Housing, food, and clothing are items that must take a prominent part in aftercare, and it is possible that in the effort to provide suitable work insufficient attention has been paid to these equally important items.

It is not difficult to appreciate the advantages which the village settlement affords with regard to post-sanatorium medical supervision and provision of the most favourable environment for tuberculous persons, but there are many who cannot or will not be admitted to these institutions. For these it is proposed that the necessary medical supervision and the opportunity for rest, nourishment, and regulated life shall be provided by the night sanatorium. This institution should accommodate from 30 to 50 tuberculous persons who have completed or nearly completed their sanatorium treatment and are fit for three or more hours' industrial employment, preferably in special factories under the Disabled Persons Employment Corporation.

Priority of admission will be given to positive cases, and particularly to those who have unsatisfactory homes or no homes at all. It is anticipated that night sanatoria will enable patients to be discharged from institutional treatment at an earlier date than if they had to return home, and they will permit the discharge of patients who are now retained in sanatoria owing to home conditions. In this way they will relieve the bed situation without increasing the nursing shortage.

For the patient the night sanatorium provides a safe means of returning to industrial work by lessening the break between the rural environment of the sanatorium and the crowded conditions of the city dwelling. It also enables the patient to continue treatment in an environment that he appreciates and is generally longing to return to whilst under treatment in the country.

Rehabilitation is not merely a matter of providing suitable work for the disabled. The unstable condition of many tuberculous workers demands routine medical examination, including radiography and a careful search for the tubercle bacillus. This is particularly necessary after catarrhal colds or influenzal symptoms. Even in long-term arrested cases a yearly check is most desirable. This means close co-operation between resettlement schemes and the chest clinics of the regional hospital boards, or rehabilitation centres will need to have their own clinics attached to the industries. Careful record-keeping at chest clinics will be necessary if the value of rehabilitation schemes is to be judged, for at present there is no statistical evidence that persons at village settlements do any better in the long run than clinically comparable cases under good domiciliary conditions, particularly if an equal amount of money and care is spent on them.

2. Assessment of Capacity for Work

That overstrain can cause a quiescent lesion to become active has been recognized for many years, and if such activity is not treated a serious breakdown in health will occur. At present only by giving a man a certain job is it possible to determine if he is capable of working. The practice, therefore, is to begin with short hours on light work, and, if the man remains healthy and shows no signs or symptoms of active disease, to increase the amount of work periodically. This method is unscientific, and, although some valuable pioneer work has been done by Brieger at Papworth, we are still a long way from solving this important problem of rehabilitation. It is necessary for the physiologist, the biochemist, and the psychologist to pool their services for research into this matter.

It can be stated that certain occupations are unsuitable for tuberculous persons, and on this point I would like to emphasize that practically all outdoor jobs are unsatisfactory for the tuberculous on account of the fatigue and exposure they involve. Other occupations that are contraindicated are the dusty trades and those involving irritating fumes, and especially those harmful dusts containing silica, as well as trades demanding work in conditions of high relative humidity or extremes of temperature. Heavy muscular work and high-pressure team-work are also undesirable These restrictions, based on observation of the behaviour of tuberculous persons who have tried working under such conditions, limit the range of employment to be recommended in a rehabilitation scheme At Papworth and Preston Hall the following industries and occupations have been carried on with successful results: printing, woodwork, clerical work, leather work, fancy goods manufacture, light engineering, and tuberculosis nursing.

Of course a condition other than the man's physical fitness has to be considered, and that is his technical ability to do the work. Where a man has to change his occupation it is usually necessary to give him a long course of instruction before he can be of any economic value. At Preston Hall a scheme has been developed by which the man can not only be trained to do a particular job but can, if he wishes, be fully apprenticed to a trade, so that eventually he becomes a skilled workman with a comprehensive knowledge of his subject. Such training is essential for young men, but it is not usually acceptable to the more elderly. The incidence of tuberculosis is steadily rising in the older age groups in males. This will probably complicate resettlement schemes, as these elderly persons do not take kindly to village settlement life and are not keen on training for a new job, although their previous occupation is often not very suitable. It is probable that the Remploy factories of the Disabled Persons Employment Corporation will be a great help to these people in the future.

The amount of work tuberculous persons can do even when their disease is arrested is usually less than that done by normal persons, and the rate at which they work is often slower. If they are employed on sanatorium staffs three tuberculous persons are needed to do the work that could be done by two normal persons. The only way to speed up production by tuberculous persons is to put them in charge of machines that do the work almost automatically and require the minimum of energy expenditure. Large amounts of capital are required to carry this out successfully and establish a productive industry. Failing this, the employment of the tuberculous is apt to develop into the nature of handicraft work which has little or no prospect

of providing a livelihood. In fact, over-concentration on handicraft work is one of the great obstacles to successful rehabilitation schemes. Unless the handicraft work is directly related to the type of work in which the patient will ultimately be trained, it is largely a waste of time and may easily create the invalid complex which prevents the man having the confidence to accept training in a trade by which he can be eventually self-supporting.

3. Danger of Infection when Disease is Active

There are two schools of thought on the infectivity of tuberculosis. One school believes that the development of active disease is determined mainly by the degree of inherent or native resistance, other important factors being the age at which primary infection occurs and the magnitude of the dose of the primary infection. If the primary infection is overcome it is thought that small reinfections tend to raise the general resistance to the disease so that active disease can occur only if the reinfecting dose is very large, and, as this is unlikely except under very close contact, it is argued that exogenous infection, other than the primary infection, plays only a small part in causing active disease in those already infected. Relapses are considered to be due to lowering of the resistance, which allows a spread of the lesion sometimes from a sudden bacillaemia arising from rupture of a tubercle into a blood vessel.

The other school puts much greater stress on the importance of exogenous infection and regards exposure even to small doses of the bacilli as dangerous. Although the evidence is by no means complete, it is probable that inherent resistance is the most important factor and that after the primary infection has been overcome only large and often-repeated exogenous infections are of any danger. If this is true it has a considerable bearing on the planning of rehabilitation schemes. It means that the tuberculous and non-tuberculous can be employed together without undue risk, provided the non-tuberculous have overcome their primary infection, are adequately nourished, have a good standard of living, and work under hygienic conditions. Tuberculosis will spread among them if any of these conditions are neglected. In other words, the soil is of more importance than the seed in preventing the spread of infection.

Even if such conclusions are correct it will be extremely difficult to apply them; for the general public have a great fear of tuberculosis, and we have to accept the fact that tuberculous persons are usually resented by their fellow workers, who always blame the known case for the development of the disease in any contact, whereas the fresh case may be entirely due to exacerbation of an old focus and have nothing to do with contact at all. Therefore, until more is known of the incidence of infection among the population and a less fearful attitude towards tuberculosis is established, it is wise not to have open positive cases in normal industry except in special circumstances that will satisfy the demands and calm the fears of the management and other employees.

Another difficulty that arises from the infectious nature of the disease is the possibility of products of the industry carrying the infection. Here again the danger is more imaginary than real, except where children are concerned, but there is evidence that woollens, furs, and books can retain the bacillus for a number of days. It is therefore unwise to teach tuberculous persons to make woollen or fur toys and children's play-mats, for, although these can be adequately sterilized when made under supervision, there is no such safeguard when the goods are made at the patient's home and sold privately. No fear of spreading the infection by polished wood or metal goods need be entertained, and there is no need to sterilize the usual products of printing, leather, or wood. But it is not good policy to employ tuberculous persons on any work connected with the preparation of food, and this includes the picking of fruits and gathering salad plants, although here again the risk has been exaggerated through repetition of unproved statements on the danger of infection.

Some day, when we have the courage to act on our convictions, this bogy of infection will be dispelled by making people realize that it is the inherent resistance to the disease that really matters once the primary infection has been overcome. If the public is to be educated along these lines we must begin by scrapping most of the pamphlets on the danger of infection and publish new ones based on recent advances in the pathogenesis of the disease.

Finance

The greatest difficulty of all in rehabilitation and resettlement is that of finance. It is best to be frank and recognize at the outset that the average tuberculous worker is a poor financial proposition to the employer unless there is capital to provide the special conditions under which he can work with safety and efficiency. In the Spero works in London, where an average of 62 mostly sputum-positive tuberculous persons are employed under sheltered conditions, there was a loss of 1,980 working days owing to sickness during 1947

Although some of the persons employed in this special factory are severely disabled, the figures give an indication of the high liability involved in employing tuberculous persons without attention to living conditions. Nevertheless it is worth while providing sheltered employment for these people, who would otherwise lounge about the streets and their homes, living under the degenerating influence of enforced idleness. But in order to employ such precarious labour heavy financial assistance is needed to maintain a sufficiently high standard of living.

To enable him to live, a disabled tuberculous person can obtain the necessary financial assistance from various sources, depending on his clinical status. Whilst he is a patient his treatment will be free and he will be entitled to national health insurance benefit and a grant up to 20s. a week for any productive work. During post-sanatorium training and rehabilitation he may receive board and lodging, national health insurance benefit, and the grant up to 20s. per week for his productive effort. The Ministry of Labour and National Service has authority to contribute to the cost of the person's rehabilitation, and approved persons in training centres get a grant of 28s. per week for a maximum period of three years; they also receive free board and lodging if residing in a hostel in the village settlement.

Some of the larger local authorities have accepted financial liability for the maintenance of persons undergoing rehabilitation at industrial settlements as part of their obligations under Section 28 (3) of the National Health Service Act. It is possible, therefore, in such circumstances to assure the training and resettlement of a tuberculous person provided the contributions from the authorities mentioned continue. Where such assistance is not forthcoming it is difficult to arrange for adequate rehabilitation. A serious obstacle may arise in the development of rehabilitation schemes if local authorities take advantage of the permissive clause in Section 28 (2) whereby they may recover charges from a person receiving aftercare services, which it is presumed includes rehabilitation, having regard to the person's means.

Any suggestion of a means test at the stage when a subject is about to begin a course of rehabilitation will cause many to refuse to accept such services. Many chest physicians believe that rehabilitation is a part of treatment, and if this is free then rehabilitation should also be free. It is hoped that those responsible will realize that the harm that will be done by application of a means test and the collection of small sums from the disabled can never be compensated by the financial gain to public funds.

Summary

Three difficulties complicate the rehabilitation of the tuberculous: (1) it is impossible to be sure that a tuberculous person has completely recovered from his infection; (2) there are no means of assessing the tuberculous person's capacity for work, except by trial and error; and (3) persons with active tuberculosis are usually infectious.

Each of these difficulties is discussed, and suggestions are made for overcoming them. The financial problem is perhaps the most difficult to solve.

PROSTATIC OBSTRUCTION*

BY

H. HAMILTON STEWART, M.A., F.R.C.S.

Surgeon, Bradford Royal Infirmary; Genito-urinary Surgeon, St. Luke's Hospital and Children's Hospital, Bradford

Over a period of eight years 2,192 patients were admitted to my wards with symptoms due to non-malignant disease of the prostate, and of these 1,960 were submitted to prostatectomy, with an overall mortality from all causes, whether attributable to the operation or not, of 3.01%. In private cases the mortality was 1.96%. The following Table gives a detailed report on these results.

Results of Treatment of 2,192 Cases of Prostatic Obstruction (Non-malignant). 1,960 Cases Submitted to Prostatectomy, With a Mortality from All Causes of 3.01%; 44.9% Admitted with Acute Retention

	No. of Patients	Percentage of Total	No. with Acute Retention in Each Group	Mortality
Perurethral prostatectomy ..	1,347	61·4%	510 (37·8%)	41 (3·04%)
Suprapubic prostatectomy ..	613	27·9%	291 (47·5%)	18 (2·93%)
One-stage	363		143	12
Two-stage	250		148	6
Suprapubic cystostomy† ..	183	8·3%	135 (73·8%)	13%
No operation	49	2·2%	—	—

A patient aged 90 had a perurethral prostatectomy successfully performed There was a consecutive series of 150 prostatectomies without a death.

† A number of these cases will be suitable for prostatectomy later.

Causes of Death following Prostatectomy

Cardiac failure ..		Malignant endocarditis	1
Coronary thrombosis	25	Cerebral abscess	1
Pulmonary embolism		Haematemesis	1
Uraemia	8	Cerebral tumour	1
Clot retention	5	Tetanus	1
Cerebral thrombosis	4	No records available	5
Shock and collapse	7		

During this period it was evident that doctors tended to send their good-risk cases to the voluntary hospital and their poor-risk cases to the municipal hospital. A surgeon working only at a voluntary hospital has therefore an unfair advantage so far as results are concerned. In the series here recorded the cases were admitted to both voluntary and municipal hospitals and to a nursing-home, and it is thus possible to judge the results of prostatic surgery carried out on a cross-section of the community.

The operations were performed by various routes—the perurethral, transvesical, and retropubic.

Acute Retention as a Result of Prostatic Obstruction

A man apparently in good health may suddenly and painfully be made aware that he suffers from a prostatic obstruction by the development of an acute retention, for which the doctor may be asked to see him for the first time. This apparent misfortune may be a blessing in disguise by directing attention to the need for radical treatment. The doctor's decision regarding the immediate treatment may profoundly influence the subsequent course of the illness. He has the choice of several methods of procedure, and I give the three best in order of preference: (A) Injection of morphine ¼ gr. (11 mg.) and immediate transportation of the case to hospital; (B) catheterization; (C) suprapubic aspiration.

(A) There is no doubt in my mind that this is the best course to adopt. The patient is immediately placed under the best conditions, and any procedure can be carried out with strict asepsis.

(B) If the patient is living in the country far from a hospital or is unfit for removal for any reason, then catheterization is permissible. The passage of a catheter should be regarded as of the same importance as a major operation. The dangers of catheterization are: (i) Trauma of the mucous membrane of the urethra, with the risk of opening venous sinuses; this may be followed by rigors and sepsis. (ii) Introduction of infection. (iii) Rapid decompression of the bladder with its attendant risks of suppression of urine and haemorrhage, particularly when an acute retention is superimposed upon a pre-existing chronic retention. (iv) Failure of catheterization.

The avoidance of trauma is of paramount importance. In the ordinary way the beak of the catheter loses its lubricant in the first part of the urethra and passes along the remainder unlubricated, and is apt to cause trauma. This difficulty can be overcome if the technique described below is carried out, and, moreover, failure of catheterization will be very rare indeed.

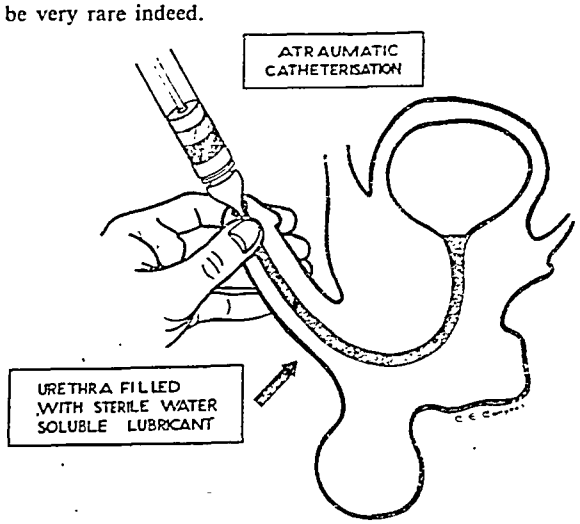

FIG. 1

*Read in opening a discussion in the Section of Surgery at the Annual Meeting of the British Medical Association, Harrogate, 1949.

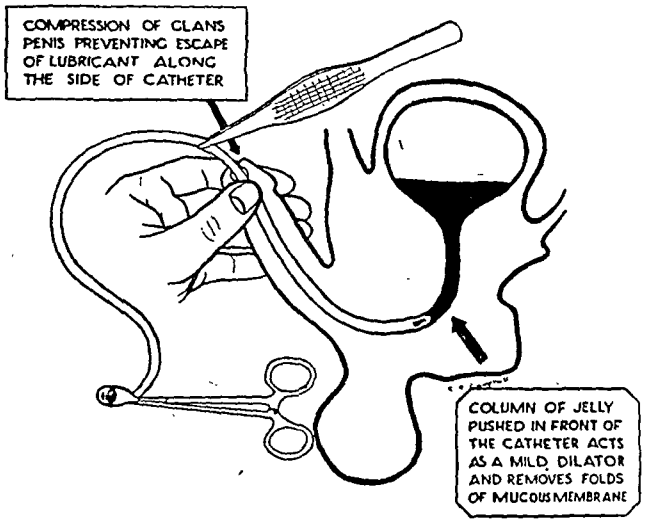

FIG. 2

About 10 ml. of sterile water-soluble lubricant is injected slowly into the urethra by means of a "record" syringe to which a rubber nozzle has been fitted (Fig. 1). The glans penis is compressed to prevent the jelly escaping. The beak of the catheter, the open end of which has been closed with artery forceps, is now introduced into the meatus and digital compression of the glans penis immediately reapplied (Fig. 2). The catheter is now advanced along the urethra, and, as an air-lock is present in the catheter as a result of closure of the end, a column of lubricant is pushed in front of the catheter. This acts as a dilator of the mucous membrane, removing any folds or light obstructions which may impede the passage of the catheter.

Repeated catheterization in these cases of retention in the hope that the patient will eventually pass urine should, except in special cases, have no place in modern treatment. Even though the congestion of the enlarged prostate should settle and the patient pass urine again, some degree of bladder-neck obstruction will persist. In due course a further retention will occur, or, if the patient is unlucky, he will live on in failing health until severe renal damage has occurred, with associated secondary cardiovascular changes. The doctor has thus merely postponed the evil day, and in the end the patient will face the operation in a poor state of health.

(C) The doctor should assure himself by percussion that the distended bladder is not intraperitoneal. After injection of a local analgesic with a fine needle into the midline of the abdominal wall a larger needle is inserted obliquely into the bladder, as illustrated in Fig. 3, and the urine from the bladder aspirated.

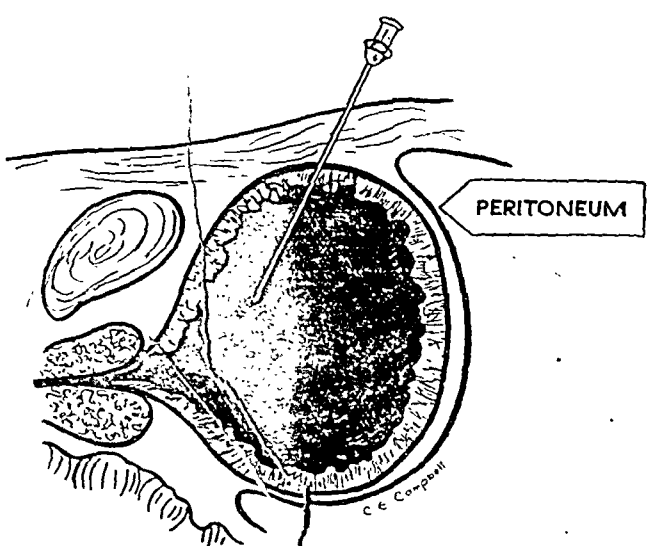

FIG. 3

The patient should then be admitted to hospital without delay.

Treatment of Acute Retention in Hospital

Three methods have been used in this series of cases (i) After calibration of the urethra an indwelling Foley's catheter (18 Charrière gauge) was inserted by the technique described. The bladder was then decompressed. In this way an emergency operation subject to difficulties which could not always be foreseen, such as cancer of the bladder complicating the obstruction, was avoided, and time was allowed for a thorough investigation of the case and an improvement of the patient's renal function. (ii) Immediate prostatectomy was performed when the retention was complicated by the existence of a tight phimosis or other conditions which made the passage of a catheter inadvisable, and when the blood urea was not raised above 100 mg. per 100 ml. (iii) Suprapubic cystostomy and decompression of the bladder was performed under local analgesia on those patients unsuited for catheterization, who were in poor general condition, or who were gravely uraemic, and any further operative treatment was delayed.

The Non-Emergency Case

Symptoms and Physical Signs

When prostatic obstruction causes retention of urine the diagnosis is easy. When it causes sufficient trouble with micturition to bring the patient to the doctor the diagnosis is generally easy. There are some cases, however, in which urinary phenomena are so slight and their onset so gradual that the patients are unaware of anything wrong with the working of the bladder. These patients seek advice because of general symptoms, such as dyspepsia or loss of appetite, lack of power of concentration, lassitude, cardiovascular disease, abdominal discomfort, backache, haematuria, etc., and the condition of the bladder-neck obstruction is discovered on routine examination. Comparatively young patients with prostatic bars of fibrous or congenital origin come into this class.

These cases of silent obstruction can very easily be missed. On abdominal examination palpation or percussion may reveal a distended bladder, but on the other hand the bladder dome may be intraperitoneal and intestine may lie in front of it. The diagnosis in several such cases has been suspected by their medical attendants only by observing displacement upwards of the pelvic colon in the radiographs taken for suspected gastric disorders. These cases will not be missed if the physician or surgeon will examine the bladder bimanually by ballottement when making a routine rectal examination.

The ordinary symptoms of prostatic obstruction are well known, and I shall not enlarge upon them. It is important, however, that the doctor should be able to tell whether the condition is a straightforward one of prostatic obstruction or is complicated by other urological lesions. Suspicion should be aroused if terminal dysuria is a symptom. Some coexisting condition, such as infection, new growth, or stones, should then be expected. Again, haematuria is not, in my experience, a common symptom of prostatic enlargement, and when occurring in a case of obstructing prostate should not be assumed to be of prostatic origin. These cases require full investigation.

The presence of pus in the urine, whether sterile or not, should always arouse suspicion. Sterile pus may be present

in the urine in a case of uncomplicated prostatic obstruction. This may be due to trauma of the mucosa from overstretching or to compression of the mucous membrane as the result of gross hypertrophy of the bladder musculature. It may, however, indicate, and often does, associated lesions such as a stone, growths, tuberculosis, etc. An infected urine in a patient who has never been catheterized should also arouse suspicion.

Examination of the Prostate

The patient should be asked to pass urine before the examination.

Left Lateral Position.—The rectum is examined. The enlargement of the prostate into the rectum is recorded (0 to 4+) and its consistence noted. Any irregularities on its surface are discovered by light palpation or, if in the substance of the gland, by deep palpation. Any adhesions to or tethering of the rectal mucous membrane are observed. The presence or absence of the median groove and lateral fornices is noted. Can the upper notch be palpated? If so, is there any perivesicular infiltration? If the finger in the rectum is now rotated so that the pulp of the finger faces upwards it is often possible to examine the base of the bladder with the side of the finger. The middle finger of the hand lies in the fold between the buttocks, and as a result the finger can be introduced a greater distance. An infiltrating carcinoma of the bladder base may be recognized in this way.

Knee–chest Position.—The lumbar curve is exaggerated. The deep palpation of the prostate is repeated, and any crepitation noted which may indicate the presence of prostatic calculi. The seminal vesicles are examined and any perivesicular infiltration, whether neo-plastic or inflammatory, observed.

Supine Position.—The legs are flexed and abducted slightly, and a bimanual examination is then made as described below.

Clinical Determination of the Amount of Residual Urine and the Size of the Prostate Gland without Cysto-urethroscopy

The dangers of catheterization and cysto-urethroscopic examinations in cases of prostatic obstruction are at last being recognized. The passage of a catheter in order to discover the amount of residual urine should be unnecessary except in very stout patients or in one who refuses to co-operate, and even then the desired information will be given by the post-evacuation cystograms. If a coexisting stricture is suspected, then diagnostic catheterization is permissible.

There is a clinical method of determining the amount of residual urine which I have found of extreme value, as it enables a decision to be made in cases of doubt, without the passage of a catheter, whether operation is advisable or not. The ability to use it requires practice and experience. The method is as follows:

The patient lies supine, with the legs flexed and slightly abducted. He should then be told that a delicate examination is to be made, which necessitates relaxation of the abdominal wall, and that he must not resist when the surgeon's fingers dip into the abdomen. The right index finger in the rectum is put as high up as possible and the tip of the finger placed in contact with the prostate or bladder base, if this can be reached. The fingers of the left hand palpate the abdomen. The upper limit of the bladder can now be determined by ballottement, the impulse being transmitted to the finger in the rectum (Fig. 4). The amount of residual urine (if present) can be assessed with a high degree of accuracy.

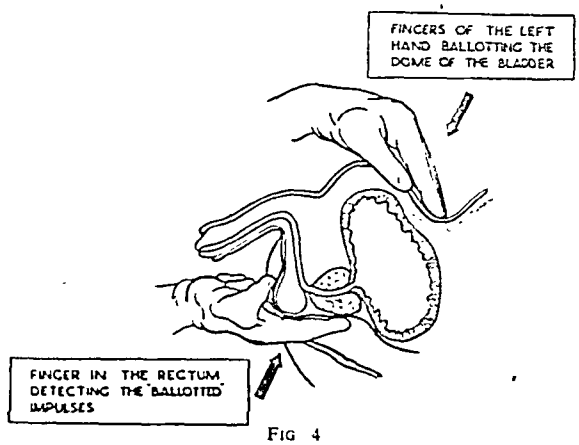

FIG 4

The fingers of the left hand now sink into the pelvis and the prostate gland is examined bimanually. The degree of intravesical enlargement of the prostate can be fairly accurately determined in the majority of cases if the patient is not too stout or the residual urine or hypertrophy of the bladder musculature is not too excessive. The size of the gland is recorded—intravesical 0 to 4+, rectal 0 to 4+

The information on the size of the prostate is of extreme value when deciding whether a perurethral prostatectomy should be performed.

The Role of Radiography

This subject is too extensive to be covered in a short paper such as this, but I should like to emphasize that the last radiographs of the series should be taken after micturition and the amount of residual urine can then be assessed

Indications for Operation

I believe that prostatectomy should be performed as soon as the diagnosis of prostatic obstruction is established, unless coexisting diseases make the expectation of life short. To delay operation until renal damage has occurred or secondary cardiovascular disease has developed is not in harmony with modern views on preventive medicine. The beneficial effect of prostatectomy upon the cardiovascular system is often most striking. Angina of effort often becomes less troublesome. In cases of hyperpiesia the blood pressure often falls, adding considerably to the patient's comfort. I wonder how many patients would have been spared a cardiovascular catastrophe, such as a coronary thrombosis, if the prostate had been removed when it first gave obstructive symptoms.

In cases of slight obstruction without marked frequency or residual urine the patient may be kept under observation It may be argued, however, that many of these cases will require operation in the end, and thus why not operate upon them early and avoid the risk of secondary changes in the kidneys and cardiovascular system? There is no doubt that many patients suffering from prostatic obstruction still come for treatment too late in the progress of the disease.

Surgical Treatment of Prostatic Obstruction: General Considerations

Care of the Indwelling Foley Catheter

The glands in the urethral mucous membrane secrete mucus, and adequate provision must be made for this to escape externally. A severe urethritis, with its serious sequelae, will follow within 48 hours of the introduction of the catheter if the meatus fits too tightly round the

any real doubt exists it may be permissible to try the effect of urethral drainage, and if the mental condition clears up completely then a prostatectomy is justifiable.

Prostatectomy

It is in my opinion a mistake to use one method to the exclusion of others. Each individual case should be judged on its own merits. Surgeons will vary in their views on choice of operation, depending to a great extent on their relative skill and experience of results with each, and also on whether they have the time, patience, inclination, and nursing staff to persevere with the difficult technique necessary for the perurethral method. Since the advent of the modern open one-stage operations, with their good results, the incentive for the younger surgeon to learn the difficult technique is not so great as it was ten years ago.

Perurethral Prostatectomy

This operation was performed in 1,347 of this series of non-malignant cases, with a mortality of 3.04%. In the nursing-home 74.3% of prostatectomies were performed by this method, with a mortality of 2.1%. The Thompson punch was used in all cases. The great majority of the really bad-risk cases, including the derelicts admitted to the municipal hospital, were operated upon by this method. It also included the bad-risk cases referred from other centres.

It would appear to be not generally known among doctors that if this operation is properly performed the obstructing gland is removed as thoroughly as by enucleation and the risk of recurrence is no greater. "Resection" of prostatic tissue with the purpose of leaving a channel through which urine can pass should be the aim only in malignant cases.

The advantages of this method are immense. The patient has no wound and he is able, if he suffers from a bad chest, to cough without pain. Adiposity does not make the operation more difficult. Patients with poor cardiovascular systems, especially those with low blood pressure in association with hardened arteries, and those with a history of thrombosis, are more safely operated upon by this method. Urinary obstructions due to fibrous and malignant prostates are also indications for its use. The patient is allowed up twenty-four hours after the operation, and the catheter is removed on the first to the third post-operative day, and in the ordinary run of cases he is discharged home eight to ten days after the operation. The operative risk is less than by open operation, and many cases considered unsuited for the latter procedure can be operated upon by this method without undue risk.

The disadvantages are equally clear. The method is difficult to learn, as the surgeon alone has the operative field in view. At least 300 operations must be performed before the surgeon can really consider himself proficient, and he must have a sound urological background and an extensive experience of cystoscopic work before attempting this method of operating. Such surgeons are not created overnight, but once the skill has been acquired great satisfaction is given to patients and surgeon alike.

A nursing team trained in this type of surgery is essential, and operations performed under adverse conditions can only bring the method into disrepute. Further, an attempt to remove a very large prostate at one sitting by this method may result in severe shock or an incomplete operation. It is thus necessary for the surgeon to determine beforehand the size of the prostate by such a method as has been described, and he is then able from experience to decide whether the gland can be removed with a Thompson punch in one sitting with ease or with difficulty, or whether it would be better removed by open operation.

The amount of tissue individual surgeons can remove at one sitting with safety varies very much with experience. The maximum amount which I have removed successfully with the punch instrument at one sitting is 116 g. I feel, however, that multiple sittings are to be avoided if possible, and I prefer to remove large glands of 70 g. or more by open operation. The average prostate weighs about 30 g., and thus the majority of cases from this point of view are suitable for perurethral removal. I usually judge that a 3+ gland (e.g., intrarectal + +, intravesical +) can be completely and easily removed down to the true capsule and will weigh between 40 and 50 g.

The case of the indwelling Fo'ey catheter is of paramount importance, and the value of frequent baths in this respect cannot be overstressed.

Open Prostatectomy

Transvesical procedures of various types in one or two stages and also retropubic operations were performed in 613 cases of this series (27.9%), with a mortality from all causes of 2.93%. The majority of the really bad-risk cases, however, were operated upon by the perurethral method.

It is of interest to note that in the early period, 1941–4 inclusive, one-stage operations were performed in 16% only of the suprapubic prostatectomies, whereas in the later period, 1945–8 inclusive, the percentage had risen to 70.9%.* The mortality did not alter to any extent—2.29% compared with 3% in the later period. Thus the more modern suprapubic methods have enabled a one-stage operation to be performed without increased risk in a greater number of cases. The reduction in the number of two-stage operations has resulted in a great saving in human discomfort and enabled many more cases to be treated in the available number of beds.

The main indications for an open operation are, in my opinion: (1) Prostatic obstruction complicated by the presence of a carcinoma of the bladder, large vesical diverticula, large vesical calculi, urethral stricture, or congenitally narrow urethra; (2) the large prostate of 70 g. or more; (3) large prostatic calculi—small prostatic calculi are no bar to the performance of a perurethral prostatectomy.

In the great majority of open operations the transvesical route was adopted. In the later years the bladder was closed in 90.5% of cases following the prostatectomy, whether it was a one-stage or a two-stage operation. In those cases in which the bladder was not closed a fine suprapubic catheter was retained until bleeding had ceased, and was then removed. The urethral catheter was retained for not longer than seven days. Suprapubic leakage did not occur in 75% of cases. In those cases in which leakage did occur the suprapubic sinus closed within 48 hours in 16%, and in the remainder within seven days from the removal of the urethral catheter.

Treatment of Carcinoma of the Prostate

Cases of carcinoma of the prostate without marked residual urine and with normal renal function were treated by the administration of synthetic oestrogens†—dienoestrol 20 mg. or ethinyl oestradiol 1–3 mg. daily—and their progress observed. Radiographs of the bones of the pelvis and blood-acid-phosphatase examinations were carried out

*A number of two-stage cases in the later series were referred for prostatectomy from other centres. A suprapubic cystostomy had already been carried out.

†When oestrogen therapy proved inadequate the testicles were removed in a few cases with temporarily beneficial results.

any real doubt exists it may be permissible to try the effect of urethral drainage, and if the mental condition clears up completely then a prostatectomy is justifiable.

Prostatectomy

It is in my opinion a mistake to use one method to the exclusion of others. Each individual case should be judged on its own merits. Surgeons will vary in their views on choice of operation, depending to a great extent on their relative skill and experience of results with each, and also on whether they have the time, patience, inclination, and nursing staff to persevere with the difficult technique necessary for the perurethral method. Since the advent of the modern open one-stage operations, with their good results, the incentive for the younger surgeon to learn the difficult technique is not so great as it was ten years ago.

Perurethral Prostatectomy

This operation was performed in 1,347 of this series of non-malignant cases, with a mortality of 3.04%. In the nursing-home 74.3% of prostatectomies were performed by this method, with a mortality of 2.1%. The Thompson punch was used in all cases. In those cases in which leakage did occur the suprapubic sinus closed within 48 hours in 16%, and in the remainder within seven days from the removal of the urethral catheter.

Treatment of *Carcinoma of the Prostate*

Cases of carcinoma of the prostate without marked residual urine and with normal renal function were treated by the administration of synthetic oestrogens†—dienoestrol 20 mg. or ethinyl oestradiol 1–3 mg. daily—and their progress observed. Radiographs of the bones of the pelvis and blood-acid-phosphatase examinations were carried out

*A number of two-stage cases in the later series were referred for prostatectomy from other centres. A suprapubic cystostomy had already been carried out.

†When oestrogen therapy proved inadequate the testicles were removed in a few cases with temporarily beneficial results.

catheter or if the catheter is too large and prevents free escape of this mucous discharge. I feel that failure to observe this principle is one of the reasons for pre- and post-operative sepsis and the development of urethral strictures, whatever type of operation is used.

After the catheter has been introduced a light dressing soaked in a water-soluble lubricant containing sulphacetamide is applied around the end of the penis and catheter and lightly bandaged or strapped in position. This lubricant prevents the mucus from drying and forming a crust which will impede further drainage of the mucus. Each day and sometimes twice a day the dressing is changed. The penis is retracted along the catheter and any dried mucus removed with "cetavlon" or weak "dettol" solution. The penis is then allowed to return to its original position and the dressing is reapplied. The patient in the pre-operative period should have daily baths.

Urethral Stricture and Congenitally Narrow Urethra

A strictured or congenitally narrow meatus can be enlarged successfully by a meatotomy. It is therefore important that the surgeon should know the calibre of the urethra behind a narrow meatus. In my clinics the urethra in the perineal and peno-scrotal regions and at the meatus is calibrated as a routine procedure. The present small Thompson punch has a size of 27 Ch., and if the measurement of the urethra is not satisfactory an open operation is preferred. If an open operation is definitely contra-indicated the instrument is inserted through an opening made in the bulb of the urethra and a perineal perurethral operation performed.

Knowledge of the size of the urethra is also of value in open operations, because the catheters are passed retrograde as recommended by Wilson Hey. The maximum size of catheter which can be comfortably taken by the urethra is known and the risk of trauma with possible stricture formation diminished.

It is often wise in these cases of a narrow urethra, after a transvesical prostatectomy has been performed, to insert a suprapubic catheter at the end of the operation as an additional safeguard instead of closing the bladder.

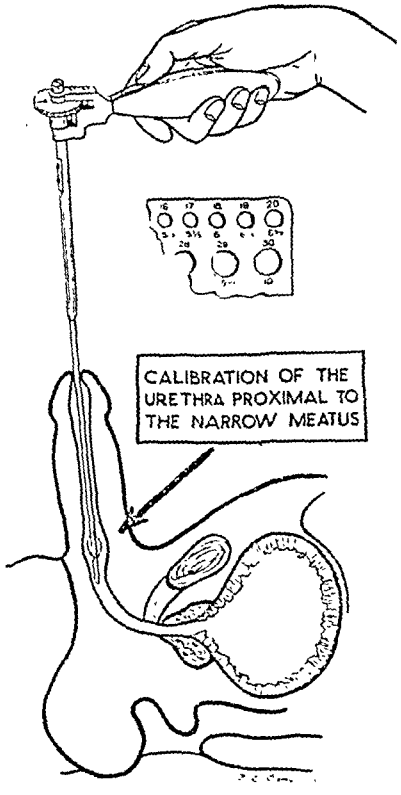

FIG. 5

Calibration of the Anterior Urethra (Fig. 5).—Sterile water-soluble lubricant is injected into the anterior urethra. The penis is held so that the penile and perineal urethrae are in line. The calibrator is passed with the blades closed. By means of the graduated wheel the blades are opened until the patient experiences a faint discomfort in the perineum. The blades are then slightly closed until all discomfort has disappeared and then reopened slowly until the patient again experiences discomfort. The reading on the graduated wheel is now noted. The instrument is then withdrawn slowly, and if the passage of the blades is impeded they are closed slightly until they can be withdrawn with ease. Absolute gentleness is necessary and the procedure must be atraumatic. In order to obtain the calibration of the various parts of the urethra in Charrière gauge the blades of the instrument are passed, after the examination, through the appropriate foramina in the metal gauge, starting with the smallest number noted on the graduated wheel. It is advisable to know roughly before the examination the number on the graduated wheel which corresponds to 27 Ch. The instrument is made for me by Messrs. Chas. Thackray, of Leeds.

The avoidance of pre-operative catheterization *of the bladder* has the disadvantage that a coexisting stricture in the bulb of the urethra may not be recognized until the time of operation.

If a surgeon over-dilates a stricture or stretches a congenitally narrow urethra in order to introduce a large-bore catheter or punch he will most certainly find that the stricture will become more troublesome in the future, and he will have transformed a congenitally narrow urethra into a strictured one.

History of a Gonorrhoeal Infection

Filmy strictures may be present, and, although an instrument or catheter may be passed without encountering any definite obstruction, blood may be noticed on the instrument. Relatively innocuous strictures may be changed into strictures that require treatment. It is advisable to perform an open operation in these cases, and a narrow urethral catheter should be used.

Prostatic Obstruction Complicated by Lesions of the Upper Urinary Tract

Severe sepsis or other urgent conditions in the upper urinary tract complicating a case of prostatic obstruction may necessitate a preliminary suprapubic drainage, followed by treatment of the renal or ureteric lesion. The prostate is removed later.

Cardiovascular Disease

Cases with cardiac decompensation usually improve rapidly once the chronic uraemia has been relieved by urethral drainage. Many cases which would appear hopeless at first become quite good operative risks after a few weeks. If fibrillation is present they are given digitalis. The use of mersalyl or "neptal" has proved a life-saving measure in some of these cases.

The cases which cause anxiety are those with gross hyperpiesia and those with a history of coronary thrombosis. These are preferably operated upon by the perurethral route. It is essential than no shock be permitted to occur during the operation and that the loss of blood be minimal. Once the blood pressure has been allowed to fall it may be difficult to get it back to normal limits, and, although the renal function may be excellent, secondary renal failure develops as a result of failure of the circulation. Intravenous saline is given by drip and also pressor substances are used irrespective of hyperpiesia.

Senility

In patients who are suffering from cerebral softening, even in an early stage, a prostatectomy, however successful as regards the urinary condition, is apt to cause further mental deterioration. They may become more confused and incontinent of urine and often also of faeces. Of all cases these have the worst prognosis, and if a patient shows signs of cerebral softening, even though these be only early, I now refuse to operate unless an acute retention is imminent. In some patients who are uraemic it may be difficult to decide how much of the mental change is due to renal failure and how much to cerebral degeneration. When

any real doubt exists it may be permissible to try the effect of urethral drainage, and if the mental condition clears up completely then a prostatectomy is justifiable.

Prostatectomy

It is in my opinion a mistake to use one method to the exclusion of others. Each individual case should be judged on its own merits. Surgeons will vary in their views on choice of operation, depending to a great extent on their relative skill and experience of results with each, and also on whether they have the time, patience, inclination, and nursing staff to persevere with the difficult technique necessary for the perurethral method. Since the advent of the modern open one-stage operations, with their good results, the incentive for the younger surgeon to learn the difficult technique is not so great as it was ten years ago.

Perurethral Prostatectomy

This operation was performed in 1,347 of this series of non-malignant cases, with a mortality of 3.04%. In the nursing-home 74.3% of prostatectomies were performed by this method, with a mortality of 2.1%. The Thompson punch was used in all cases. The great majority of the really bad-risk cases, including the derelicts admitted to the municipal hospital, were operated upon by this method. It also included the bad-risk cases referred from other centres.

It would appear to be not generally known among doctors that if this operation is properly performed the obstructing gland is removed as thoroughly as by enucleation and the risk of recurrence is no greater. "Resection" of prostatic tissue with the purpose of leaving a channel through which urine can pass should be the aim only in malignant cases.

The advantages of this method are immense. The patient has no wound and he is able, if he suffers from a bad chest, to cough without pain. Adiposity does not make the operation more difficult. Patients with poor cardiovascular systems, especially those with low blood pressure in association with hardened arteries, and those with a history of thrombosis, are more safely operated upon by this method. Urinary obstructions due to fibrous and malignant prostates are also indications for its use. The patient is allowed up twenty-four hours after the operation, and the catheter is removed on the first to the third post-operative day, and in the ordinary run of cases he is discharged home eight to ten days after the operation. The operative risk is less than by open operation, and many cases considered unsuited for the latter procedure can be operated upon by this method without undue risk.

The disadvantages are equally clear. The method is difficult to learn, as the surgeon alone has the operative field in view. At least 300 operations must be performed before the surgeon can really consider himself proficient, and he must have a sound urological background and an extensive experience of cystoscopic work before attempting this method of operating. Such surgeons are not created overnight, but once the skill has been acquired great satisfaction is given to patients and surgeon alike.

A nursing team trained in this type of surgery is essential, and operations performed under adverse conditions can only bring the method into disrepute. Further, an attempt to remove a very large prostate at one sitting by this method may result in severe shock or an incomplete operation. It is thus necessary for the surgeon to determine beforehand the size of the prostate by such a method as has been described, and he is then able from experience to decide whether the gland can be removed with a Thompson punch in one sitting with ease or with difficulty, or whether it would be better removed by open operation.

The amount of tissue individual surgeons can remove at one sitting with safety varies very much with experience. The maximum amount which I have removed successfully with the punch instrument at one sitting is 116 g. I feel, however, that multiple sittings are to be avoided if possible, and I prefer to remove large glands of 70 g. or more by open operation. The average prostate weighs about 30 g., and thus the majority of cases from this point of view are suitable for perurethral removal. I usually judge that a 3+ gland (e.g., intravesical 1+, intravesical 1+) can be completely and easily removed down to the true capsule and will weigh between 40 and 50 g.

The case of the indwelling Foley catheter is of paramount importance, and the value of frequent baths in this respect cannot be overstressed.

Open Prostatectomy

Transvesical procedures of various types in one or two stages and also retropubic operations were performed in 613 cases of this series (27.9%), with a mortality from all causes of 2.93%. The majority of the really bad-risk cases, however, were operated upon by the perurethral method.

It is of interest to note that in the early period, 1941-4 inclusive, one-stage operations were performed in 16% only of the suprapubic prostatectomies, whereas in the later period, 1945-8 inclusive, the percentage had risen to 70.9%.* The mortality did not alter to any extent—2.29% compared with 3% in the later period. Thus the more modern suprapubic methods have enabled a one-stage operation to be performed without increased risk in a greater number of cases. The reduction in the number of two-stage operations has resulted in a great saving in human discomfort and enabled many more cases to be treated in the available number of beds.

The main indications for an open operation are, in my opinion: (1) Prostatic obstruction complicated by the presence of a carcinoma of the bladder, large vesical diverticula, large vesical calculi, urethral stricture, or congenitally narrow urethra; (2) the large prostate of 70 g. or more; (3) large prostatic calculi—small prostatic calculi are no bar to the performance of a perurethral prostatectomy.

In the great majority of open operations the transvesical route was adopted. In the later years the bladder was closed in 90.5% of cases following the prostatectomy, whether it was a one-stage or a two-stage operation. In those cases in which the bladder was not closed a fine suprapubic catheter was retained until bleeding had ceased, and was then removed. The urethral catheter was retained for not longer than seven days. Suprapubic leakage did not occur in 75% of cases. In those cases in which leakage did occur the suprapubic sinus closed within 48 hours in 16%, and in the remainder within seven days from the removal of the urethral catheter.

Treatment of Carcinoma of the Prostate

Cases of carcinoma of the prostate without marked residual urine and with normal renal function were treated by the administration of synthetic oestrogens†—dienoestrol 20 mg. or ethinyl oestradiol 1-3 mg. daily—and their progress observed. Radiographs of the bones of the pelvis and blood-acid-phosphatase examinations were carried out

*A number of two-stage cases in the later series were referred for prostatectomy from other centres. A suprapubic cystostomy had already been carried out.

†When oestrogen therapy proved inadequate the testicles were removed in a few cases with temporarily beneficial results.

at two-monthly intervals. If residual urine was considerable or renal impairment evident the cases were observed weekly, and if rapid improvement did not occur a perurethral resection was carried out. Cases suffering from acute retention were as a rule submitted to perurethral resection after preliminary catheter drainage if necessary, and oestrogen given by the mouth subsequently. If microscopical examination revealed an undifferentiated carcinoma, deep *x*-ray therapy was often given in addition to synthetic oestrogen by the mouth, as my experience had suggested that this form of cancer was less likely to be kept in check by oestrogen therapy alone.

Results in a Series of 176 Malignant Cases Admitted to Hospital

145 (82%) submitted to operation:
- 101 (70%) .. Perurethral resection .. .. Deaths 3 (2·8%)
- 30 (20%) .. Suprapubic prostatectomy .. Deaths 2 (6·6%)
- 14 (10%) .. Suprapubic cystostomy

31 (18%) not submitted to operation:
- 25 (14% of total) .. .. .. Dienoestrol alone
- 7 .. .. Died in hospital

Summary

A clinical method of diagnosis to prevent cases of prostatic obstruction being missed is described. The treatment of the acute cases and the indications for the various types of operations are discussed.

The paper is based upon a series of 2,192 consecutive cases of bladder-neck obstruction due to non-malignant disease of the prostate, of which 1,960 cases were submitted to prostatectomy, with a mortality from all causes of 3.01%. The perurethral method was used in 68.73% of cases (74.3% in private cases).

The perurethral method is considered the method of choice in the majority of cases.

The treatment of cancer of the prostate is discussed.

Prostatic obstruction should be relieved as early as possible before secondary changes occur in the renal and cardiovascular systems: too many cases still come for treatment late in the progress of the disease.

I wish to thank Sisters Deacon, Meek, and Walker, without whose care, organization, and enthusiasm these results could not have been obtained. My grateful thanks are also due to Mr. Hadda, past registrar, and to Messrs. Breckenridge and Harrison, present registrars, for operating upon many of the cases, and also to Mr. Harrison for compiling the results. Last, but not least, I thank the many house-surgeons who have helped me.

When Sir William Marshall delivered his presidential address at the annual conference of the Scottish Association of Executive Councils on September 30 he said that they heard from all sides about the heavy demands on the services of the doctors, and it was clear that these demands were excessive and sometimes even unreasonable (*Scotsman*, October 1). Doubtless when the novelty of the scheme had worn off the rush to the doctor's surgery might lessen, but every consideration should be given to methods of reducing claims on the doctor's time for non-medical purposes. The call for certificates was using up much time which should properly be devoted to clinical work. Waste and extravagance must be checked. Some rearrangements might be necessary to bring home to the people the need for limiting their demands to what was in actual fact necessary. Claims for repairs, both to dentures and spectacles, were increasing month by month. Executive councils had a right in cases of negligence to refuse replacements or to make the applicant pay part of the cost, but this implied inquiry, which was both difficult and distasteful. As the State had already met the primary cost, it might well be left to the individual to meet the charge for repairs, with perhaps some power of the executive council to waive this in cases of real need. Whether it would be possible to make any charge in the case of drugs was more doubtful, but with regard to appliances there might be some provision to entitle the executive council to insist on payment of at least part of the cost.

MULTIPLE MYELOMA

A NOTE ON EIGHT CASES

BY

D. P. DEGENHARDT, M.R.C.P.
Chief Assistant in Medicine

AND

D. SHEEHAN, M.D., M.R.C.P.
Senior Registrar
West Middlesex Hospital, Isleworth, Middlesex

[WITH PHOTOGRAVURE PLATE]

Until recently multiple myeloma was considered a comparatively rare disease. Its incidence was given as 0.03% of all malignant growths (Brewer, 1948), and the post-mortem incidence of three large hospitals was 16 in 19,000 (0.084%) Since the introduction of marrow biopsy as a means of diagnosis more cases have been recognized, and in the last few years larger series have been published.

We were struck by the frequency of the disease at this hospital. Eight cases were diagnosed during 1948, five of them coming to necropsy during that year and two since then. This gives a post-mortem incidence for 1948 of 5 in 442 (1.13%). This high figure may, however, be to a certain extent due to selection. It represents 2% of all deaths from malignant disease occurring in the hospital—a substantially higher proportion than previous figures would suggest.

There have been very full reports in the recent literature by Atkinson (1937), Snapper (1943), Harwood Stevenson (1948), and others. We are therefore confining our remarks to some points in these eight cases which appear to be of special interest.

Symptoms and Signs

First, the way in which these patients presented. Most of them complained of pain in the lower part of the back, general weakness, and vomiting. The last-named symptom has not been mentioned much by other writers. It occurred with normal blood-urea levels and was not caused by treatment. Anaemia was also prominent, and was normocytic or microcytic. Collapsed vertebra was one of the presenting signs in two patients, but the incidence and distribution of backache had no relation to the location of this lesion

We confirm the well-recognized fact that the E.S.R is very rapid, reaching 80–120 (Westergren) in the first hour One of our patients, however, had an E.S.R. of only 15 and 25 in the first and second hours respectively. She was one of the most rapidly progressive diffuse cases, but her plasma proteins were normal. In another case extremely rapid agglutination prevented readings.

Albuminuria was present in every case, and Bence-Jones proteins were found in seven patients, though their presence varied from week to week. Most writers give figures of from 50 to 75% for the occurrence of Bence-Jones proteins, but Magnus-Levy (1932), giving a figure of 80%, points out the difficulty of their demonstration at times, especially in the presence of albumin.

A finding that has not often been reported is the presence of a raised C.S.F. protein, which was seen in the three cases which had lumbar punctures. Cabot (1934) found a raised C.S.F. protein in one patient, who, however, had tumours growing into the subarachnoid space. Only one writer—Magnus-Levy (1933)—reports the undoubted presence of Bence-Jones proteins in the C.S.F. We tried to demonstrate this, but were unable to do so in any of the three cases examined.

Blood Chemistry and Cytology

The blood chemistry may be of help in the diagnosis, although the findings are not always characteristic. According to Magnus-Levy (1933), 50 to 60% have raised plasma proteins, due to a raised globulin and sometimes to increased fibrinogen (Reimann, 1932). About the same number have a raised serum calcium with a normal or even increased phosphorus. This helps to distinguish them from cases of osteitis fibrosa cystica, in which the phosphorus is usually lowered. The increased calcium is probably due not only to the mere increase of calcium bound to globulin but also to the destruction of bone by neoplasm (Gutman and Gutman, 1936). This is borne out in one of our patients, who had a raised calcium with normal plasma proteins (Case 8).

In this series also there was a great variation in the appearance of the cells, but in all cases the cells were easily recognized as myeloma-plasma cells (Plate, Figs. 1 and 2). While in a normal marrow there may be 1 to 2% of plasma cells, the percentage of these cells varies from 20 to 90% of the cells in the marrow of these patients. It is interesting to note that in one of the patients the diagnosis was made only after the second marrow biopsy, the first one containing only 3% of plasma cells. The cells varied from typical plasma cells to much larger cells with less densely staining nuclei, not always eccentric and showing nucleoli (Fig. 1). The general features of the cells were, however, the abundant basophilic cytoplasm with frequent degenerative changes such as vacuolization. Sometimes a perinuclear clear area, or "Hof," was seen, and usually the nucleus was eccentrically placed. Multinucleated cells were frequent.

Table giving Details of Cases. (W.R. and Kahn negative in all cases. Alkaline phosphatase expressed as King–Armstrong units. Serum phosphorus expressed as inorganic PO_4.) Albumin was present in urine in every case

The diagnosis rests, of course, on the demonstration of myeloma cells in bone marrow, usually obtained by sternal puncture, but in one of our cases obtained by puncture of the iliac crest, as the sternum was too tender (Case 8). Since the introduction of marrow biopsy and the staining of smears by the Romanowsky method it seems to be fairly generally agreed that the myeloma cell is related to the plasma cell and probably derived from the reticulum cell (Boyd, 1944; Bayrd, 1948). The pleomorphism, not only from case to case but also in individual cases, probably accounts for the previous reports of such varieties as lymphoblastic and erythroblastic myeloma.

Two of the cases were of the diffuse type described by Ulrich (1939), Churg and Gordon (1942), and others, which even at necropsy may be difficult to recognize without marrow studies. In one of these, in spite of typical punched-out translucent areas in the radiographs, a fractured sternum, and two collapsed vertebrae, there was at necropsy no evidence of the usual whitish gelatinous tumours, but the whole marrow was dark red. Microscopically, it contained a very high percentage of plasma cells (Case 8). Case 5 had a macroscopically normal marrow. Some of these

cases may show little or no abnormality in the radiographs, except perhaps some general decalcification (Snapper, 1943).

The kidneys show typical changes, which are now thought to be primarily due to a blockage of the renal tubules with Bence-Jones proteins (Ehrich, 1932; Bell, 1933; Snapper, 1943). Other writers (Thannhauser and Krauss, 1920; Perla and Hunter, 1930) think the changes are due to a nephrosis akin to amyloid disease. These changes, consisting of an accumulation of eosinophil material in the collecting tubules, which are distended, and an increase in interstitial tissue, were well seen in four of these cases (see Fig. 3).

In seven cases the course of the illness was under 12 months, and treatment with stilbamidine or pentamidine had no effect, though relieving pain in three cases.

ADDENDUM

Since this paper was written three further cases have been studied. All had a raised C.S.F. protein. In one (Case 11) the C.S.F. protein was raised while the plasma proteins were still normal. In these cases the C.S.F. may be a more sensitive index of raised proteins than the plasma. In cases presenting with neurological signs the finding of a raised protein in the C.S.F. may be misinterpreted and the widespread nature of

Treatment

Treatment is still very unsatisfactory. Geschickter and Copeland (1928) report the average duration of the disease as two years in 425 cases, the longest recorded being five and a half years. Remissions were sometimes seen. In this series the duration was much shorter, being five to twelve months in all except one patient, who has now lived for sixteen months since the onset of symptoms. Recently stilbamidine and pentamidine have been tried, and varying reports on their efficiency have been published. Snapper (1946) was responsible for introducing them. Recent reports by Brewer (1948) and Propp *et al.* (1949) of cases treated with stilbamidine were not very favourable, and certainly did not indicate remission or arrest of the disease, though pain was relieved in some cases. Some of the patients in our series were so treated, with indifferent results. Pain was relieved in three out of five cases, but the treatment did not appear to influence the course of the disease.

Summary

Eight cases of multiple myeloma were seen in the course of 12 months, five of them coming to necropsy, giving a post-mortem incidence of 1.13%.

The method of presentation was by backache, weakness, vomiting, collapsed vertebra, anaemia, and albuminuria.

Seven out of eight cases had Bence-Jones proteins, and all had albumin in the urine.

Three cases in which the C.S.F. was examined had a raised protein.

The cytology of the bone marrow is discussed, with special reference to two diffuse cases.

Four cases showed typical changes in the kidneys.

the lesion overlooked. Laminectomy proves technically difficult, and, we understand, such patients do badly. Laminectomy is probably contraindicated.

We wish to record our thanks to Dr. N. F. Coghill for help and encouragement in the preparation of this paper and for making Cases 2, 4, and 6 available to us. The other cases were made available through the kindness of Dr. Marjorie Warren (Cases 1 and 3), Dr. J. A. Torrens (Case 7), and Dr. M. M. Deane (Cases 5 and 8). We also wish to thank Dr. A. C. Spence for the marrow studies, Dr. A. C. Counsell for the pathological investigations, Dr. M. Lubran for the biochemical investigations, and Mr. D. A. Vinten for the photomicrographs.

FATAL POISONING OF AN INFANT BY ANTI-ANAEMIC PILLS CONTAINING IRON, MANGANESE, AND COPPER

BY

J. H. PRAIN, M.B., Ch.B.

(From the Department of Pathology, University of St. Andrews, and Royal Infirmary, Dundee)

[WITH PHOTOGRAVURE PLATE]

The use of iron in therapy dates back to Celsus, who treated splenomegalic anaemia by the administration of the water in which smiths had drenched their red-hot irons. It was not until 1746, however, that Menghinis discovered the presence of iron in the blood and so gave a reason for a form of therapy which has come into active use only within the last two generations. The benefits of vigorous ferro-therapy in special instances are so striking that iron is now too often used as treatment for any anaemic condition. More recently it has been found that traces of copper and manganese are necessary adjuvants in iron therapy, and the three metals are now available in the form of pills which are stable, effective, and elegant. There is little doubt that these pills are prescribed very frequently, as is shown by the fact that in this region, with a population of approximately 400,000, the five main hospitals issued approximately 500,000 of these pills in a period of six months. Unfortunately, the figures of the quantity prescribed by the practitioners are not available.

That ingested iron is not without danger is seen in Kachin Beck disease (Hiyeda, 1939), a disease occurring among children in Manchukuo and North Korea, due to continuous chronic overdosage with iron in the drinking-water. Acute overdosage by ingestion of pills containing iron, manganese, and copper has been recorded as causing death in three infants (Forbes, 1947; Thomson, 1947). The present case is presented because it allowed the investigation of certain points not available for study in the earlier cases, and its occurrence emphasizes again the need for every doctor and pharmacist, when supplying such pills (e.g., fersolate), to warn the mother of the extreme danger to infants.

Case Report

At approximately 7.30 p.m. on February 8, 1948, a girl aged 1 months swallowed some pills with which she had been play- ?. Each of the pills contained ferrous sulph. exsic. 3 gr. 2 g.), copper sulphate 1/25 gr. (2.6 mg.), and manganese phate 1/25 gr. (2.6 mg.). The exact number swallowed is fortunately not known, as the mother seized the remainder threw them in the fire. The child became very drowsy vomited. The vomit was at first green and later became wn. She was admitted to Dundee Royal Infirmary at 0 p.m.—i.e., two hours after ingestion of the pills.

On admission she was pale and drowsy, but not cyanosed; she made no resistance to examination. The pulse was rapid but regular, the respiratory system seemed normal, the abdomen was soft and nowhere tender, the pupils reacted normally, and there was no evidence of neck rigidity.

Shortly after admission she vomited, the vomitus being brown in colour and streaked with bright-red blood, but there was no further vomiting after 10 o'clock that evening. She was treated immediately on admission with chalk mixture and sodium bicarbonate.

The next day she seemed to be much better, sitting up in her cot, taking notice of her surroundings, and playing with her toys. Two dark tarry stools were passed during the day, but there was no diarrhoea. On the morning of the 10th she was found to be much worse, with cyanosis of the lips and moist accompaniments to the breath sounds at both bases. Sulphadimidine ("sulphamezathine") and penicillin were given, but her condition deteriorated rapidly and she died at 1.10 p.m., 39 hours after ingestion of the pills.

Post-mortem Examination Report (21 hours after death).—"The body is that of an adequately nourished infant with slight cyanosis of the lips but no jaundice in skin or conjunctivae. The *stomach* shows an area of extreme congestion, containing numerous small haemorrhagic points with some oedema, and closer study reveals that in this area mucosal damage of varied degree is present. This area is situated in the middle third of the stomach, nearer the greater curvature, and extending upwards on the anterior and posterior walls. From this central area of intense change a lessening degree of reaction spreads over the remainder of the stomach. The stomach contains approximately 15 ml. of dark-brown coffee-ground material. In the *small intestine* there are a few areas of congestion and swelling, but this is not so marked as in the stomach; the three main areas of reaction are situated on the anterior wall of the third part of the duodenum, in the proximal jejunum, and as a diffuse slightly affected area in the proximal ileum It is noted that the Peyer's patches are not affected. The ileum contains dark tarry faecal material. The *liver* (2 lb., or 0.9 kg.) is pale, flabby, and greasy to touch. The *spleen*, which is normal in size, weight, and consistence, presents a mottled appearance, light spots flecking the cut surface.

"The *lungs* show a considerable degree of congestion, and in the right upper lobe a small area of haemorrhage is present on the anterior border. The *heart* shows dilatation of the right auricle and ventricle, and the myocardium is generally soft and flabby. The valves are competent. The *pericardium* and *thymus* seem normal, as do the *gall-bladder*, *pancreas*, and *suprarenals*. The *kidneys* are pale, but apart from this appear healthy, with normal ureters; the bladder, which is also normal, contains 18 ml. of clear urine. The *reproductive organs* are normal, as are the *brain* and *meninges*."

Special Examinations.—Analysis of the urine, gastric and caecal contents, and the bile for iron, copper, and manganese resulted as follows:

	Gastric Contents	Caecal Contents	Bile	Urine
Fe	0·455%	0·529%	0·0158%	0·0037%
Cu	0·0099%	0·00235%	0·00452%	0·00044%
Mn	Present	0·0024%	0·0057%	None

That the high gastric and caecal iron content is not entirely the result of the haemorrhage from the mucosal damage is shown by the presence of copper and manganese in the same samples. The "metabolic route" of the manganese is indicated by its obvious presence in the bile and its absence from the urine; the copper content of both bile and urine agrees with its recognized route of excretion. Since these estimations were made on isolated specimens obtained at necropsy it is unwise to compare them with normal excretion values, but they are much higher than those considered normal.

Histology.—The main lesions occur in the gastro-intestinal tract. In the stomach, the area of acute gastritis described above is seen to consist of localized areas of severe necrosis (Plate, Fig. 1) of the gastric mucosa with a striking impregnation of the adjacent reticulum by iron (Fig. 2), recalling the impregnation described in the pulmonary reticulum in haemosiderosis (Scott Park *et al.*, 1947). There is also oedema of the submucosa, and under the areas of necrosis the veins show thrombosis with iron impregnation of their walls (Fig. 3). Deeper still, the as yet not thrombosed vessels show thickened endothelium which contains masses of iron granules. The liver (Fig. 4) shows a widespread and surprisingly uniform fatty change and some iron is present, but in no great amount—much less than used to be seen in the typical case of pernicious anaemia. The presence of copper and manganese in the liver can perhaps be deduced from the fact that the reaction with sulphide shows more metal in the hepatic cells than is revealed

by Perls's reaction for iron. The tubules of the kidney show cloudy swelling but no other lesion, and iron could not be demonstrated. The only other significant finding in the viscera was necrosis of the Malpighian corpuscles of the spleen.

Discussion

Although previous reports have dealt with the toxicology of this condition, this new case raises some points in the clinico-pathological synthesis that are of interest.

It appears from the microscopical examination that once the gastric mucosa is damaged the iron escapes from the lumen into the tissues and leads to thrombosis of the submucosal veins; this thrombosis would seem to act as a block, in that comparatively little iron has been found in the liver. None the less, it is difficult to escape the conclusion that the gross fatty change in the liver is due to absorption of substances from the lumen through the areas denuded of mucosa, or possibly from the breakdown products of the mucosa itself. The extent and degree of the change in the liver seem scarcely sufficient to explain the fatal issue, but in view of the failure to find any other cause of death one might assume that the damaged liver, although capable of sustaining life for some time, was not capable of maintaining its detoxicating process in the continued presence of this absorption. The final collapse of the liver, by allowing access of the absorbed substances to the rest of the body, led to the sudden exitus. The necrosis of the Malpighian corpuscles is probably associated with that generalized toxaemia.

The present case emphasizes again two important clinical points. First, it is of the utmost importance to begin treatment urgently for the sake of the gastric mucosa, as it seems probable that the gastric mucosa is the first and main line of defence of the liver. In this respect it is of interest to note that a recent paper described a case of recovery after the ingestion of similar pills in which treatment was started at once by the patient himself, and little evidence of liver damage could be found (Roxburgh, 1949). The histological findings in the present case fail to provide any suggestions for specific therapy, and one can merely repeat the probable value of early administration of alkali to form insoluble hydroxides. It would seem that dimercaptopropanol (BAL) is unlikely to be of help (McCance and Widdowson, 1946) in such cases; it was used by Roxburgh, who makes no claim, however, for its value.

The second point of clinical importance is the occurrence of a misleading period of improvement and apparent well-being before a rapidly fatal termination. A similar false recovery occurred in one of Forbes's cases, and the fact should perhaps be stressed that in treatment of such cases this period of betterment neither lessens the gravity of the prognosis nor permits any relaxation of therapeutic activity.

Summary

A case is described of fatal poisoning of an infant by pills containing iron, copper, and manganese.

The clinical course showed a period of apparent recovery followed by sudden death: this misleading sequence occurred also in one of the previously reported cases.

The histological findings suggest that the destruction of the gastric mucosa leads to lethal hepatic damage.

It is the duty of doctors and pharmacists to warn parents of the grave risk to infants presented by these visually attractive pills.

I wish to thank Professor A. C. Lendrum for his help and advice in the preparation of this paper and Mr. A. Dargie, Dundee City Analyst, for the analysis of the specimens of gastric and caecal content, bile, and urine. I am also grateful to Dr. J. Thomson, Royal Infirmary, Dundee, for the clinical details, and to Mr. J. W Corkhill for the photomicrography.

SYNOVIAL OSTEOCHONDROMATOSIS

TWO UNCOMMON EXAMPLES

BY

J. F. CURR, M.D., F.R.C.S.Ed.

Formerly Temporary Assistant Surgeon, Royal Infirmary, and Leith Hospital, Edinburgh, late Orthopaedic Specialist, R.A.M.C.

[WITH PHOTOGRAVURE PLATE]

Synovial osteochondromatosis is a well-recognized condition, but the two cases reported here presented some unusual features.

Case 1

The patient, a man aged 23, had a history of stiffness of the right shoulder for about six months, associated with occasional slight pain, but with no obvious cause beyond some trivial injuries in the past. On examination there was a complete absence of any movement in the right shoulder-joint.

Radiological examination disclosed enormous numbers of opaque loose bodies, of varying size and density, occupying the entire shoulder-joint and extending into the subscapular bursa and the synovial sheath of the long head of the biceps. Synovial osteochondromatosis was diagnosed (Plate, Fig. 1). There was no abnormality elsewhere.

At operation the right shoulder-joint was exposed through a long anterior incision. On opening the bulging synovial membrane loose bodies were scooped out by the dozen, but many

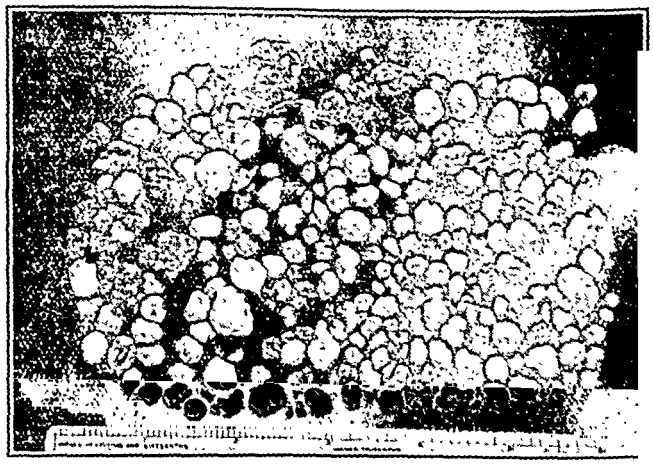

FIG. A.—Case 1. Photograph of loose bodies after removal.

still attached to it had to be avulsed or dissected out. An attempt at synovectomy was abandoned owing to tough adhesions and haemorrhage, but the whole of the synovial sheath of the long head of the biceps was excised and also as much as possible at the site of the reflection of the synovial membrane on the humerus. All loose bodies were removed after a complete exploration.

Pathological Condition.—The entire synovial membrane was ed, rough, and oedematous. The earliest lesions were tiny odules and small sessile excrescences, and were most pro- ounced at the reflection of the synovial membrane and in he bicipital groove. Larger bodies were hanging in clusters, nd other solitary bodies possessed a mere hairlike pedicle. The largest bodies, up to 2 cm. in diameter, were lying com- letely detached and mobile within the joint. Those with any legree of pedicle were red and still retained a blood supply, ut the actual loose bodies were yellow and more polished; ll were somewhat rounded, with a pitted irregular surface. There were more than 350 osteochondromata, including several lusters not yet independent (Fig. A); very tiny ones still mbedded in the synovial membrane were difficult to count ccurately. Their total weight was 67.5 g. There was marked steoarthritic lipping at the edge of the articular cartilage of the umerus, together with an erosion of the cartilage in the centre of the head where a loose body had been impacted.

Histological examination of a portion of the synovial nembrane with the earliest changes demonstrated well-marked ancellous bone formation, as well as fibrous tissue and carti- age; there was extensive proliferation of the synovial tissue (Fig. 2).

Several of the loose bodies were examined radiologically after emoval and showed a central opaque nucleus, surrounded by nore dense peripheral laminae of calcification.

Progress.—Healing was uninterrupted, and no remaining loose odies were found on subsequent radiological examination. Two months after operation a moderate degree of all move- ments had been restored, but further follow-up proved impossible. The formation of the osteochondromata appeared so active that it is almost certain that they will develop again, necessitating a second operation. A stiff shoulder is the prob- able final result, especially as osteoarthritis is already established.

Case 2

This patient, a man aged 55, sustained a trivial injury to the left ankle, and two weeks later was seen on account of swelling and moderate disability. Radiological examination revealed several opaque loose bodies, posterior to the ankle-joint, which were typical of synovial osteochondromata (Fig. 3). There were also early changes of osteoarthritis in the ankle-joint.

At operation a postero-medial incision was made and the loose bodies were found lying in a large bursa communicating with the synovial tendon sheath of flexor hallucis longus. Some were quite loose and others were attached in clusters to the synovial lining, which was otherwise healthy. All the osteo- chondromata were removed and the entire bursa was excised. A good recovery followed.

Comments on the Condition

e of Origin.—Henderson and Jones (1923) observed the site of reflection of the synovial membrane is the nmon site of origin of osteochondromata within a joint; is is the region of differentiation in the foetus, and is the most favourable situation for disarrangement of cells which in later life may take on properties not normally possessed. The findings in Case 1 are thus clearly in confirmation.

Nature of the Condition.—Osteochondromatosis is now generally accepted as being a benign neoplasm, developing from embryonic rests or from a metaplasia of connective-tissue cells. Although malignant synovial tumours are well known, it is seldom appreciated that malignant change may supervene on osteochondromatosis on very rare occasions; Geschickter and Copeland (1936) and Brailsford (1948) refer to cases in which a sarcoma developed. Bennett (1947) showed the necessity for following up all benign neoplasms or other tumour-like lesions of synovial tissue because of the risk of subsequent malignancy and also because there may be difficulty at first in distinguishing histologically between benign and malignant conditions. In Case 1 recurrence seems almost certain owing to the activity of the growth of osteochondromata, and it is interesting to speculate on the possibility of ultimate malignant change.

Growth of Bone.—The growth of bone and the increase in size of the osteochondromata are in keeping with the opinions of Greig (1931). He maintained that bone forms before a loose body becomes detached, for the reason that bone formation requires an adequate blood supply, not available after the loose body is once free. Any increase in size after detachment is then due to increase in the amount of cartilage, which can derive nutrition from synovial fluid. Calcification, as distinct from ossification, may occur there- after in the periphery of the loose body.

Involvement of Shoulder-joint.—This is a very rare site, coming in order of frequency after knee, elbow, ankle, and hip joints. Albee (1927) removed 64 loose bodies, and Henderson and Jones reported another case, both being followed by recurrence. The condition was also demon- strated by de Lorimier (1943), Behrens (1947), and Brailsford.

Involvement of Bursae and Tendon Sheaths.—Being closely related to joints embryologically, these are subject to the same pathological conditions and may become the site of loose bodies. Osteochondromatosis is not common in them and may occur independently or in association with a similar joint lesion. References have been made, among others, by Henderson and Jones, Geschickter and Cope- land, Buxton (1923), Janik (1927), and Shepherd (1943).

Numbers of Loose Bodies.—A solitary osteochondroma may occur. Very large numbers, however, have been recorded, such as 700 by Timbrell-Fisher (1927), 1,047 by Berry (quoted by Timbrell-Fisher), and 415 by Boyd (1947) all in the knee, and 1,000 by Brailsford in the hip. As a rule the number is much smaller, and the figure of at least 350 in Case 1 is well above the average.

Treatment

Operation is required if there is to be any hope of recovery of function of the joint or prevention of osteo- arthritis. According to Timbrell-Fisher, the process of loose-body formation may end as suddenly and mysteriously as it began, and the results of operation are good provided the condition is not then progressive; otherwise there is recurrence and a second operation becomes necessary. Henderson and Jones extracted ten loose bodies from a shoulder-joint through a very small posterior incision, but, though possibly effective in certain instances, this limited type of exposure does not seem applicable in the presence of large numbers, especially if still attached to or involving synovial extensions of a joint. Wilmoth (1941) performed a partial synovectomy, with removal of loose bodies, in most of his cases, but was uncertain regarding the prevention of recurrence. A total synovectomy is the best method of ensuring against recurrence in a case with extensive involve- ment, but it is not attainable in all joints nor under such conditions as in Case 1.

Involvement of a bursa is easily treated by its complete excision. In a tendon sheath, simple removal of loose bodies is the usual treatment, but occasionally total excision of the synovial lining is possible.

Summary

Two uncommon examples of synovial osteochondromatosis are reported. In one case the shoulder-joint was involved most extensively, over 350 loose bodies being removed. In the other the loose bodies were in a bursa in direct communication with

a tendon sheath at the ankle; recovery followed removal of the osteochondromata and excision of the bursa.

I wish to acknowledge my indebtedness to Messrs. A. H. Baird, who carried out the photography.

A STUDY IN VISUAL DEFECTS IN YOUNG CHILDREN

BY

P. A. TYSER, M.D., B.S., D.P.H.

Senior Assistant Medical Officer, Area No. 3 (Tottenham), Middlesex County Council

AND

T. W. LETCHWORTH, M.D., F.R.C.S.

Visiting Ophthalmic Surgeon to the Local Education Authority

It is evident from the annual returns of the school health service that amblyopia and strabismus form a large proportion of cases of defective vision. It is the purpose of this paper to describe a simple method whereby gross errors of refraction in children under the age of 5 can be ascertained. We demonstrate that this method is accurate enough to be used on a wide scale, that a large number of children in the age group discussed suffer from gross errors of refraction, and that it is important from a preventive aspect that they should be detected and treated as early as possible in order to achieve good results and prevent deterioration and the development of other conditions. Except in cases of suspected strabismus, hypermetropia under 2D and astigmatism under 0.75D was not corrected; in all other cases correction was made, the conditions being referred to as gross errors of refraction.

We are not concerned here with the finer analysis of the degrees of the errors of refraction and their age distribution, this is of secondary importance to this investigation.

The sight of children is usually examined when they are 7 to 8 years old by the Snellen type test in the course of routine medical inspections. Before this age treatment may be sought only when attention is drawn to the child's eyes by the occurrence of squint or because defective vision is thought to exist. A squint of the ordinary concomitant type associated with hypermetropia is usually manifest between the ages of 18 months and 5 years. At the age of 12 months a child should have acquired the power of fixation. Now, if something prevents that being acquired, nystagmus will occur, but during the next few years the full visual acuity will have to be developed. In cases of a high degree of astigmatism a distinct image is not formed on the retina and full visual acuity cannot be developed. Also with anisometropia the child will not focus the ametropic eye and the same will follow.

It is therefore of great importance that such conditions should be recognized as soon as possible, since by correcting such errors at the earliest opportunity the final result will be much better. After the age of 8, if no correction has been carried out, there will be in these cases a considerable degree of amblyopia, which may be difficult or impossible to overcome. Furthermore, by correcting high degrees of hypermetropia many cases of potential squint may be forestalled. Experience has also shown that if one child in a family has a gross error of refraction it is likely that some of the other children will also have errors requiring correction, and it is the custom of one of us (T.W.L.) to inquire into family histories and to examine all the children of a family in which one child is found to have a gross error of refraction.

The number of cases of amblyopia discovered in school entrants indicates that a far more intensive investigation should be made of the eyesight of the pre-school child. Some special test, easily applied and quickly performed, is required to ascertain those children who are suffering from grosser errors of refraction. One of us (P.A.T.) undertook the retinoscopy examination of all children present in the day nurseries, nursery schools, and classes in the borough.*

Method and Scope of Eye Investigation

Retinoscopy was performed with a plane mirror without using a mydriatic. The children were examined in a darkened room seated on a chair at arm's length. First the movement of the red reflex was noted in vertical and horizontal meridians. Movement against the mirror in any meridian in either eye was noted as "myopia" and referred to one of us (T.W.L.) for further examination. If movement occurred with the mirror then the procedure was repeated using a +2D lens held in turn immediately in front of the child's eyes, movement in any meridian in either eye being noted as "hypermetropia" and referred for further examination. It was found that having the children attend in batches of ten alleviated anxiety and that it was possible to examine 60 children in the course of an hour.

The upper age limit was taken as the age of 5 in January, 1949. Accommodation for 567 children exists in the day nurseries, nursery schools, and classes. Owing to illness and other reasons 87 were absent at the time of the survey and 10 became too emotionally disturbed to be examined. Of the 470 children examined, 10 were excluded from the final results, eight being over the age of 5 and two who were ascertained to have defects failing to keep several appointments for further examination. The results of the remaining 460 examinations are considered here.

Results

Table I shows the analysis by sex and age of the examinations made. The numbers in the age groups are considered too small for further analysis. The 460 children comprised 247 boys and 213 girls, and in each case 19

*We wish to acknowledge our indebtedness to Dr. G. Hamilton Hogben, to the borough education officer, and to the head teachers and matrons of the nursery schools and classes and day nurseries in Tottenham for their invaluable assistance.

visual defects were discovered—i.e., 7.7% and 8.9% respectively, with an overall percentage of 8.26. The number of children who were already receiving treatment for defective vision at the time of the investigation was 11 (five boys and six girls), or 2.39%. A further 33 cases were revealed by the survey; of these, 27 were later confirmed—i.e., 5.87%.

Table II provides an analysis of the defects found.

Low hypermetropia	5	0
Myopia	2	0
Mixed astigmatism	2	0
Simple hypermetropia	1	0
No significant error	6	0
Totals	33	11

Conclusion

The results of this investigation are to be regarded as a "pilot" survey. Children attending nurseries may not be representative of the whole child population in the age groups examined. Further, a retinoscopy examination without the use of a mydriatic cannot give entirely accurate information about the state of the ocular mechanism. The method employed was devised and used as a simple and speedy technique to discover grosser errors of refraction. Despite its limitations it is contended that the method is justified and suitable for use on a wide scale in the annual examination of children of pre-school age.

Dr. Leonard Scheele, Surgeon-General of the U.S. Public Health Service, is reported to have stated recently that 1949 will be the worst year for infantile paralysis in the history of the United States, with cases reaching a total of 40,000 to 45,000. This will be a 50% increase over the infantile paralysis cases reported last year, and he feared that figures may be even higher next year and in the years to come. In the 10 years before 1943 there was only a moderate incidence of infantile paralysis in the U.S.A., but since then there has been a marked upward trend.

ACUTE ADRENAL INSUFFICIENCY AFTER ADRENALECTOMY FOR PRE-PUBERTAL VIRILISM

BY

B. VICTOR JONES, M.B., B.S.

Late House-surgeon, Charing Cross Hospital.

The following case is reported because it must represent closely the results of total extirpation of the adrenals in man.

Case Report

A girl aged 6 was found to be suffering from typical pre-pubertal virilism when first seen on November 8, 1944. The urinary 17-ketosteroid excretion was 12.3 mg. a day. Laparotomy was performed; this confirmed her sex and showed both adrenals to be much enlarged. Left adrenalectomy was carried out and the ketosteroids fell to 8.3 mg. a day. Her physical condition, however, did not improve, and her psychological condition became so difficult that her parents found it impossible to manage her. She was therefore readmitted at the age of 9¼ for further treatment.

Although her general appearance was that of a normal girl of this age there was marked enlargement of the clitoris and the vagina was rudimentary. A heavy growth of pubic hair was present. Her mental ability was only that of a child two years younger, and she behaved in an excessively rowdy way. Her voice was unusually deep. The urinary 17-ketosteroids were now 26 mg. a day.

The right adrenal gland was explored on February 20, 1945, and found to be about five times the normal size. A portion 1½ by 1 in. (3.75 by 2.5 cm.), representing just under half the gland, was resected with the diathermy needle and the cut edge of the remainder of the gland oversewn with catgut. The wound was closed without drainage. A small wound was accidentally made in the pleura; it was immediately closed. An intravenous glucose-saline drip was started.

Ten hours after operation her condition was quite satisfactory and the intravenous drip was discontinued. But the pulse and respiration rates began to rise during that night, and by 24 hours after operation the blood pressure had fallen to 75/45. Her pulse was weak and rapid, and she was drowsy but rational. She was sweating slightly and her skin felt warm. It was now noticed that generalized pigmentation of the skin was developing. As the day went on she became noisy and restless, and her temperature rose to 103° F. (39.4° C.). A right-sided

pneumothorax was present. Two 10-ml. doses of "eucortone" were given during this day, but had little noticeable effect. During the night her condition became steadily worse. The blood pressure remained at 75/45, and her pulse became irregular and at times uncountable at a rate of about 180 a minute. The respiration rate rose to 60 a minute. She was delirious and incontinent of urine.

On the morning of the second day after operation her condition was so grave that the ward sister thought she was not likely to live for more than an hour. The pulse was uncountable and the respiration rate still 60; the blood pressure was now only 50/20. A deep generalized pigmentation of the skin was present; it was of café-au-lait colour and evenly distributed over the whole body. Nevertheless, her ears and lips remained a good pink colour and the pale grey-blue cyanosis seen in cases of severe shock—e.g., after severe burns—did not develop. The haemoglobin was 55%, so it was evident that the haemoconcentration of shock was not developing.

She was given 10 ml. of eucortone intravenously, and one hour later her general condition was noticeably better. A further 15 ml. was therefore given immediately, and further improvement followed. An intravenous glucose-saline drip was started again and eucortone, 30-ml., was introduced with it four-hourly. During the day she vomited several times, but the total amount brought up in the post-operative period could not have been more than 1 pint (568 ml.). She passed no urine, and by the evening oedema of the face, particularly about the eyelids, was beginning to develop. She was catheterized, but only about

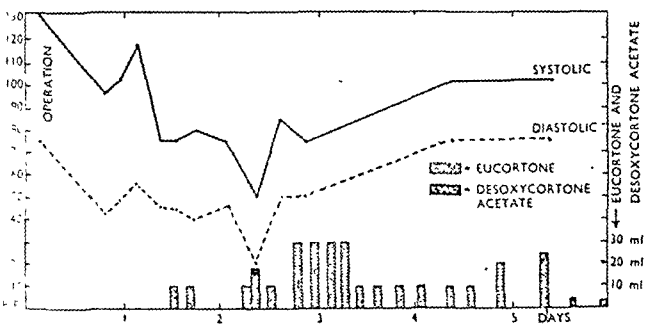

Chart showing blood pressure and the course of adrenal cortex replacement treatment.

50 ml. of urine was obtained. This was of average concentration and contained albumin but no sugar or ketone bodies. The urinary chlorides were 3 g. per 100 ml., and a blood sample taken at the same time contained only 292 mg. of sodium per 100 ml. (normal 325 mg.).

Her condition continued to improve during the night, though she was noisy and delirious and required heavy sedation. By the next day, the third after the operation, the blood pressure was rising and the pulse and respiration rates were falling. There was marked oedema of the face but none of the limbs or sacral area. She began to take fluids by mouth and passed 30 oz. (950 ml.) of urine. On the fourth day she was rational and sleepy, and her general condition had very much improved. She was taking food by mouth, and the blood pressure had risen to 102/75. The oedema was subsiding, but the pigmentation still remained.

From then onwards she made rapid progress. The eucortone was reduced to 10 ml. four-hourly on the third day after operation, and she was given 20 ml. on the fourth; it was stopped altogether on the fifth day, and desoxycortone acetate, 2 ml. (10 mg.) was given thrice daily for five days followed by 2 ml. daily for two days. Common salt, 6 g. daily, was given while she received desoxycortone acetate. The oedema had disappeared by the sixth day. The pigmentation gradually faded; it had become faint by the eighth day and had disappeared by the sixteenth, by which time she was afebrile and in excellent health. The total amount of eucortone given was 275 ml. The urinary ketosteroids on March 16 were 8.4 mg. a day.

Discussion

It will be seen that, three years after one adrenal had been removed, resection of about half of the remaining gland was followed by a crisis similar to those which occur in Addison's disease. It did not occur immediately after the operation, but began within 12 hours of it. It is presumed to have been due to defunctioning of the remaining part of the gland by oedema, with the added possibility of thrombosis of the adrenal vein by the diathermy used in the excision.

Pigmentation occurred within 24 hours of the operation and was maximal within 48 hours of it; it was generalized and even, and in colour and depth closely resembled that of known cases of Addison's disease which were in the ward at the time. It had almost disappeared eight days after the operation. This was the most striking feature of the crisis.

The pigmentation of Addison's disease has been accounted for as follows. Adrenaline is normally prepared in the adrenal medulla from tyrosine, which is stored in the skin. If the adrenal medulla is destroyed and no adrenaline is formed the tyrosine is not used up and accumulates in the skin, where a tyrosinase converts it into melanin (Wright, 1945). The fact that pigmentation occurred so rapidly in this case seems to support the theory that adrenaline is secreted continuously in man.

The patient's condition during the crisis was rather like that in surgical shock, but the extremities remained warm and pink instead of cyanosed, and there was marked hyperventilation. The whole clinical picture resembled the Waterhouse-Friderichsen syndrome closely, but no petechiae were present, livid cyanosis did not occur, and she responded well to treatment with adrenal cortex extract (Martland, 1944). The pigmentation seen in this case has not been described in either of the above-mentioned conditions.

Summary

A case of pre-pubertal virilism is described; it was treated by adrenalectomy, followed later by removal of part of the remaining adrenal gland.

A crisis resembling those of Addison's disease occurred during the first few days after the second operation; it responded well to treatment with eucortone, desoxycortone acetate, and intravenous glucose-saline. Recovery followed.

I wish to thank Mr. L. R. Broster for permission to publish this case and for his help in preparing the paper.

In future national insurance cards will not be stamped by patients in mental institutions or by the staff of the institutions on the patients' behalf. The Ministry of National Insurance will not ordinarily examine liability for contributions until after a patient's release, unless the next of kin wishes to pay or an application for benefit is made. These arrangements have been agreed by the Ministries of Health and National Insurance, and are conveyed to mental institutions in Circular 95/49. The insurance cards should be returned to the local national insurance office, which will issue to the institution a form for each patient instead of a card. If the patient is transferred to another institution the form should accompany the patient, and on the patient's discharge or death it should be returned to the local office named on the form. The next of kin of the patient or the person to whom correspondence about the patient is sent will have an opportunity of paying national insurance contributions on the patient's behalf if he wishes to do so.

Medical Memoranda

An Operation for Femoral Hernia

The discussion on femoral hernia in the *British Medical Journal* of October 23 and November 6 and 13, 1948, has prompted me to describe, before I intended doing so, a method of closing the femoral canal which I have been using and which I think fulfils all the requirements of an operation for femoral hernia. In it no foreign unabsorbable material is used, with the occasional disappointment which this sometimes engenders. (Patients seem more disgruntled at having a chronic sinus from foreign material than if they had had a recurrence.) The canal is closed at the inlet by a living membrane that is always at hand. Very large openings are easily closed by this means.

The method puts no strain on the external oblique muscle. Any method that pulls down the inguinal ligament to Cooper's ligament in the high operation, or to the pectineal fascia in the low-type operation, produces a strain on the external oblique tendon and is often followed by rupture of the fibres here and a weakening of the inguinal canal. Hence the tendency to inguinal hernia after high or low operations in which the inguinal ligament is pulled down to one of these structures. When I have used the method here described there has been no subsequent discomfort.

Technique

I recommend the method for trial as I feel that no individual surgeon sees a sufficient number of femoral herniae in a limited time to appraise a method fully. The operation can be done with comfort for the patient and surgeon under local analgesia. A point in the simplification of the operation is the use of the Trendelenburg position.

The most satisfactory skin incision is one over the inguinal canal and curving down over the femoral sac at its inner end. This allows a good vision of the inguinal canal area and of the sac and the pectineus muscle with its coverings.

The sac is accurately freed from the surrounding fat and fascia; if large, the redundant part of the sac should be excised to facilitate the sac's being drawn up through the canal. The external oblique muscle over the inguinal canal is then incised as in inguinal hernia. The cord or round ligament is drawn up, the transversalis fascia is incised, and the extraperitoneal fat is exposed. The neck of the sac entering the femoral canal is gently pulled on, and by careful teasing the whole sac is pulled up from the femoral canal. The bladder is carefully separated from the sac on the inner side and a high closure of the sac made. The ligated portion and peritoneum are now pushed upward and the ileopectineal line, with Cooper's ligament, is exposed. A good exposure is obtained with the Trendelenburg position.

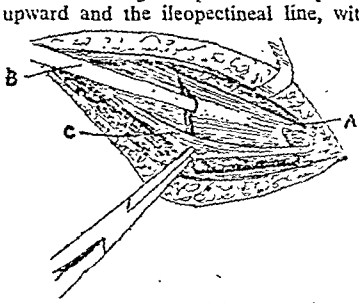

FIG. 1.—The pectineal fascia has been separated from the underlying pectineus muscle and is ready to be drawn upwards above the inguinal ligament. A=Superior ramus of pubes with Cooper's ligament. B=Blunt dissector raising fascial flap. C=Inguinal ligament.

Cooper's ligament extends down over the pectineus, where it blends with the pectineal fascia. The fascia is exposed from the ileopectineal line above to below the inguinal ligament by gentle wiping with a gauze swab. The medial border of the iliac and femoral veins is noted. This gives the outer border of the fascial leaf to be utilized and defines the breadth of fascia to cover the opening of the femoral ring. The fascia is incised along this line from Cooper's ligament to below the inguinal ligament, and the fascia is separated from the bone and underlying pectineus muscle by blunt dissection.

The fascia is cut across about ¾ in. (1.9 cm.) below the inguinal ligament. It can now be pulled upwards so that it hangs freely above except where it is hinged at Cooper's ligament (*Fig. 1*). This flap, which is naturally strong, is then laid without tension along the upper concave edge of the inguinal ligament and fixed here with two or three interrupted 40-day catgut sutures (Fig. 2). This effectively blocks the upper opening of the canal. The transversalis fascia is sutured accurately back in position and the external oblique muscle incision closed (Fig. 3).

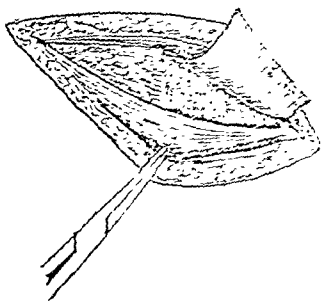

FIG. 2.—The flap of fascia has been pulled up and is ready to be laid upon the upper surface of the inguinal ligament.

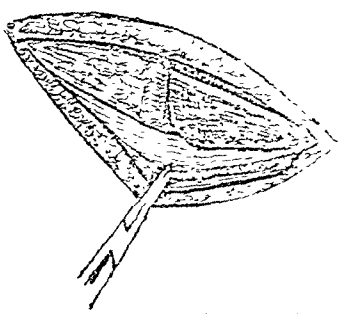

FIG. 3.—The flap of fascia has been sutched to the upper concave edge of the inguinal ligament.

Comment

Since writing this short description of an operation for femoral hernia I have read A. K. Henry's article (*Lancet*, 1936, 1, 531) where he suggests an operation in which he uses the pectineal fascia in much the same way for the closure of the upper orifice of the femoral canal. Unfortunately, his unusual mode of approach has evidently overshadowed the suggested method of closure of the canal, for it has not been mentioned in any of the recent articles on the subject, and this short description is published with a view to popularizing this method of closing the canal. Henry's method of approach does not give a good view of the pectineal fascia and renders the operation difficult. The most satisfactory incision is the one I have described.

G. D. F. McFADDEN, M.Ch., F.R.C.S.

Branchial Fistulae

Proximally blind lateral cervical fistulae opening in the vicinity of the anterior border of the sterno-mastoid, and extending a variable distance up the neck, are not uncommon. Apart from their persistence and occasional discharge, they cause little disability, and where excision is indicated the procedure is simple provided their origin lies external to the carotid sheath. Consideration of the development of the visceral arches confirms the view that these branchial fistulae are probably derived from the cervical sinus, which in the embryo is normally shut off from the pharynx by a septum of tissue, the cleft membrane. Consequently the presence of a complete fistula communicating internally with the pharynx and presenting an external opening in the neck may be considered a rare condition.

CASE REPORT

The case is that of a girl aged 16 who complained of a small discharging sinus in her neck. She stated that to her knowledge it had been present since birth, and that periodically it became more noticeable and discharged a clear coloured fluid for several days.

On examination a barely noticeable papule was present over the anterior border of the left sterno-mastoid and situated about 2 in. (5 cm.) above the suprasternal notch (Fig. 1). There was no discharge at the time, and it was found impossible to get a very fine probe into what was apparently a closed punctum. However, extending upwards from this towards the angle of the jaw was a slight but just visible cord-like thickening comparable in diameter to an ordinary lead pencil. On asking the patient to open her mouth and upon milking this thickening upwards, a good teaspoonful of whitish fluid was seen to exude from the region of the supratonsillar fossa.

FIG. 1.—Opening of branchial cyst in neck.

Under anaesthesia and after packing off the pharynx, a large ureteric catheter was passed with ease through a visible ostium opening above the left tonsil. Lipiodol was injected, and a subsequent radiograph (Fig. 2) confirmed the provisional diagnosis of a complete branchial fistula communicating with the pharynx.

FIG. 2.—Lateral view of fistula after injection of lipiodol.

COMMENT

Surgical ablation of such a fistula entails a moderate-sized incision and a careful dissection in the region of the internal carotid artery, due respect being given to the proximity of both the glosso-pharyngeal and the facial nerves. Access to the pharyngeal closure of such a fistula is best aided by lateral displacement of the tonsil by means of a finger in the mouth. The mere presence of a branchial fistula is in my opinion no indication for surgical intervention, and certainly before the latter is contemplated the extent of the tract at least should be investigated.

I wish to thank Dr. G. A. Borthwick, superintendent of the Northern Hospital, N.21, for permitting me to publish this case.

WILLIAM ROTHWELL, F.R.C.S., F.R.C.S.Ed.

Hyperpyrexia Complicating Infantile Eczema

Cases of sudden death in patients suffering from infantile eczema have been reported from time to time. Schwartz (1934) reviewed 10 such cases, and Feer (1904) reported others. These deaths seem to have been due to intercurrent infections, such as septicaemia, bronchopneumonia, or gastro-enteritis, which have run a more rapid course in these children than is usual. None of these appear to resemble the following case.

CASE REPORT

The patient, a boy aged 13 months, had suffered from eczema since birth. On admission he had large patches of eczema, partly impetiginized, covering the greater part of all four limbs, the trunk, the face, and the scalp. The skin was treated with compound zinc ointment, and chloral was given by mouth to allay restlessness. The eczema improved greatly during the first week. The skin, however, became dry and showed powdery desquamation.

On the eighth day after admission a convulsion occurred, together with vomiting, pin-point pupils, and the passage of faeces. The skin felt extremely hot, and on taking the temperature in the rectum the mercury reached the end of the thermometer. Repetition with a second thermometer produced the same result. Both were subsequently tested, and the temperature required to bring the mercury to the end of the thermometers was found to be 110° F. (43.3° C.). Tepid sponging was started immediately, and the temperature was plotted every fifteen minutes. After half an hour the temperature was 106° F. (41.1° C.), and after one hour 104.8° F. (40.45° C.). Consciousness was regained four hours from the onset of the convulsion. The temperature was then 100° F. (37.8° C.).

Investigations were carried out to exclude intercurrent disease. The E.S.R. was 12 mm. in one hour. The urine showed a trace of albumin, but no abnormality was found in the C.S.F., the differential white cell count, or in the *x*-ray picture of the chest.

Progress was uneventful. A low-grade pyrexia persisted, but the eczema cleared except for a small patch on the shoulder. At the time of writing, eleven months later, the child is still attending as an out-patient. His skin remains dry and there are a few eczematous patches.

COMMENT

Hyperpyrexia is a possible and dangerous complication of infantile eczema in which a large proportion of the body surface is involved. In this case the combination of hyperpyrexia, pin-point pupils, convulsions, and unconsciousness also raises the possibility of a pontine lesion. Vasomotor spasm in the pons offers a reasonable explanation of the transitory nature of the signs.

Gratitude is expressed to Dr. F. A. Bryning, medical superintendent of Hackney Hospital, for permission to publish this case, and to Dr. F. L. Lydon, consultant dermatologist, for advice on its presentation.

TOPICS IN BACTERIOLOGY

Bacterial and Mycotic Infections of Man. Edited by René J. Dubos, Ph.D. (Pp. 785; illustrated. £2 5s.) Philadelphia and London: J. B. Lippincott Company. 1949.

Microbiology and Man. By J. Birkeland, Ph.D. Second edition. (Pp. 525; 54 figures. £1 7s. 6d.) London: Baillière, Tindall and Cox. 1949.

Bacterial Metabolism. By Marjory Stephenson, Sc.D., F.R.S. Third edition. (Pp. 398; illustrated. £1 10s.) London: Longmans, Green and Company. 1949.

A galaxy of celebrities—thirty-four in all—has contributed to *Bacterial and Mycotic Infections in Man*, edited by Dubos, which is perhaps the most important new work of its kind for many years and is already to be found in many laboratories in the U.S.A. So much has happened in bacteriology recently that the revision of older books is an unsatisfactory process, and entirely new accounts, written by leading authorities from fresh viewpoints, have emerged to present their subjects in a new light. The most valuable parts of this book are thus the introductory chapters: by Dubos and Pappenheimer on the morphology and physiology of bacteria, by McLeod and Pappenheimer on the "properties of bacteria which enable them to cause disease," and by Francis on the "response of the host to the parasite." Other sections on allergy, immunity, and immuno-chemistry are equally useful. There is also a chapter on blood groups, but why this should be included in a work on microbic infection is not clear.

The descriptive part of the book consists of twenty-four chapters, each describing a genus or group of micro-organisms. Other subjects discussed are the normal flora of mucous surfaces, sterilization, chemotherapy, epidemiology, and diagnostic proceedings, the whole being preceded by a full account from Murray of the history of the subject.

The pitfalls of multiple authorship have to a great extent been avoided. The book is coherent and nearly complete and the fullness with which each subject is treated is more or less uniform, although some authors, such as Conant, writing on mycoses, are lavish with their illustrations while others use few or none. Three genera not described are *Lactobacillus*, *Pfeifferella*, and *Fusiformis*. Possibly the first of these is excluded as non-pathogenic, but glanders and melioidosis are surely as important as *Bartonella* infection, and the various Gram-negative anaerobes sometimes classed as *Fusiformis* are interesting and frequent causes of infection and are rarely described adequately. It is perhaps unjust to criticize omissions in such a volume: it is neither a bench book nor a work of reference, but rather an educational book for the advanced student or the teacher. No reader will fail to profit from some of its stimulating pages.

The alliterative title of Birkeland's book *Microbiology and Man* suggests a popular work rather than a textbook. That it is intended for the use of students is expressly stated, but the nature and object of the course these students may be pursuing are not specified. Bacteriology is extensively taught in the U.S.A., both as a pure science and in its several applications to industry, and many textbooks in use there are intended for non-medical undergraduates and are consequently often unsuited to the needs of medical schools. Despite its extensive preoccupation with human disease, the proper function of this book seems to be to describe pathogenic species and their effects for the benefit of students whose main interests lie elsewhere. The descriptive middle section has a strong clinical bias, surprising in the work of a non-medical author, whose unfamiliarity with disease as such is occasionally betrayed—of typhoid fever he says that "there may be perforations of the intestinal tract followed by haemorrhage"; of anthrax, "if the abscess is opened and allowed to drain, healing may be fairly prompt"; and of cerebrospinal fever, "epidemics last two to three years." The introductory chapters on bacterial morphology and physiology are good, like the concluding ones on food, water, soil, and sewage: that on bacterial warfare is, perhaps fortunately, brief and non-committal.

Medical bacteriology has developed on utilitarian lines and uses methods of cultivation whose origin is empirical. Only in fairly recent times has the nutrition of bacteria been thoroughly studied, but there has now grown up a branch of the science with an imposing bulk of knowledge on this subject, using terms which the ordinary medical bacteriologist, unless he happens to be more than usually well versed in chemistry, may find hard to follow. A leading pioneer in this development was the late Marjory Stephenson, whose *Bacterial Metabolism*, much amplified in its third edition, is a standard work. It is indispensable to any inquirer in this field, and though concise and simply written is almost encyclopaedic in scope—the bibliography occupies 62 pages. The time is perhaps not far distant when the practical fruits of these fundamental studies will profoundly affect medicine as well as other spheres of applied bacteriology. Their results are already discernible in several directions, notably the rational approach to chemotherapy.

PRACTICE OF ANAESTHESIA

Modern Practice in Anaesthesia. Edited by Frankis T. Evans, F.F.A.R.C.S., D.A. (Pp. 566; illustrated. £2 10s.) London: Butterworth and Co. 1949.

Dr. Frankis Evans has succeeded in the difficult task of harnessing talented individuals to produce a well-balanced book. Here and there a tendency is noticed for a member of the team to steer his own course, but the general performance loses nothing by this occasional display of high-spiritedness. British anaesthetists may well be proud of this production by their London colleagues, and they will be prouder still when a few imperfections, some of them minor, are eliminated. If the editor re-reads one of his references (to Bier) he will no doubt correct some historical inaccuracies in the opening paragraph of his chapter on spinal analgesia. Fig. 25 is wrongly labelled, and the anonymous illustration No. 77 is worthy neither of the book in general nor of the excellent section on epidural anaesthesia in particular. The suggestion that carbon dioxide absorption technique must be used to achieve controlled respiration (p. 134) is a harmless inaccuracy, but the statement on p. 330 that 2% procaine is self-sterilizing is a serious blot. In addition to these factual errors, I believe the chapter on anaesthesia for bronchoscopy to be poor, and I found some of the whirligig diagrams of that admirable teacher, Dr. Galley, more inclined to confuse than clarify. I must confess to being allergic to pages of chemical formulae, and I believe it would be more in keeping with the sound common sense of the book to delete those unintelligible to anyone but a profound organic chemist—alternatively, if the full formula of *d*-tubocurarine chloride must be given on p. 81 there is no need to repeat it in full on pp. 82 and 212.

R. R. MACINTOSH.

CASE REPORT

The case is that of a girl aged 16 who complained of a small discharging sinus in her neck. She stated that to her knowledge it had been present since birth, and that periodically it became more noticeable and discharged a clear coloured fluid for several days.

On examination a barely noticeable papule was present over the anterior border of the left sterno-mastoid and situated about 2 in. (5 cm.) above the suprasternal notch (Fig. 1). There was no discharge at the time, and it was found impossible to get a very fine probe into what was apparently a closed punctum. However, extending upwards from this towards the angle of the jaw was a slight but just visible cord-like thickening comparable in diameter to an ordinary lead pencil. On asking the patient to open her mouth and upon milking this thickening upwards, a good teaspoonful of whitish fluid was seen to exude from the region of the supratonsillar fossa.

FIG. 1.—Opening of branchial cyst in neck.

Under anaesthesia and after packing off the pharynx, a large ureteric catheter was passed with ease through a visible ostium opening above the left tonsil. Lipiodol was injected, and a subsequent radiograph (Fig. 2) confirmed the provisional diagnosis of a complete branchial fistula communicating with the pharynx.

FIG. 2.—Lateral view of fistula after injection of lipiodol.

COMMENT

Surgical ablation of such a fistula entails a moderate-sized incision and a careful dissection in the region of the internal carotid artery, due respect being given to the proximity of both the glosso-pharyngeal and the facial nerves. Access to the pharyngeal closure of such a fistula is best aided by lateral displacement of the tonsil by means of a finger in the mouth. The mere presence of a branchial fistula is in my opinion no indication for surgical intervention, and certainly before the latter is contemplated the extent of the tract at least should be investigated.

I wish to thank Dr. G. A. Borthwick, superintendent of the Northern Hospital, N.21, for permitting me to publish this case.

R. R. MACINTOSH.

A TEXTBOOK OF ORTHOPAEDICS

Essentials of Orthopaedics. By Philip Wiles, M.S., F.R.C.S. (Pp. 486; 7 coloured plates and 365 text-figures. £2 2s.) London: J. and A. Churchill. 1949.

Mr. Wiles has tackled the difficult task of telling undergraduates, junior residents, and general practitioners what is essential in orthopaedics—probably with the knowledge that not one of his colleagues in the same field would wholly endorse his choice of material. But there can be no doubt that he has been unusually successful and has produced a book that will prove popular because it so nearly achieves its object.

The arrangement of the chapters is unconventional. The author begins with a superb essay on the difficult and neglected subject of postural defects, and passes without any loss of continuity to another good chapter on pain in the back. This is followed by articles on disorders of the spine and the other joints. Here the trouble begins, for a regional approach inevitably leads to repetition in descriptions of conditions that may affect almost any joint, such as osteo-arthritis and tuberculosis. Even then the author finds it necessary to discuss these diseases in later chapters, in which he ties up the loose ends and is again repetitive. In writing a book of this kind the dilemma is perhaps insoluble, but it is probably best to stick to the old-fashioned plan of placing the general chapters before those concerned with regional topics.

The book contains a happy mixture of the author's own views with those of others. Mr. Wiles reveals himself as a good teacher; he speaks with authority from personal experience and at the same time shows his intimate knowledge of all that is significant in the world of orthopaedics. It is therefore unfortunate that his book is unadorned with detailed references to the many excellent papers from which he has chosen so wisely.

The book is pleasant to read; the reader finds himself carried along by language of engaging simplicity, so much so that it seems captious to criticize details. But a few examples must be mentioned—neuresthenia, haemophylia, aneurism, fusilade, and champfer are indications of lax proof-reading. Paget's quiet necrosis is not a synonym for osteochondritis dissecans, and the semilunar cartilages cannot be described as concentric. Most of the illustrations are excellent, though some of the radiographs and a few of the other pictures could have been better. The general quality of production is a great credit to the publishers.

The demand for the book is likely to be considerable. A second edition may soon be called for and the author will then have the chance of making his book unquestionably the best of its kind. If a reviewer may presume to give advice in an undertaking that is beyond his own capacity, I would suggest attention to the following points: rearrangement of the chapters; elimination of textual errors; verification of some techniques and opinions ascribed to other authorities; more references; and raising all the illustrations to the high standard the author has set himself.

H. J. SEDDON.

CARDIAC CATHETERIZATION

Cardiac Catheterization in Congenital Heart Disease. By A. Cournand, M.D., Janet S. Baldwin, M.D., and A. Himmelstein, M.D. (Pp. 108; illustrated. $4.00 or £1 2s.) New York: The Commonwealth Fund. London: Geoffrey Cumberlege. 1949.

It was a pleasure and a privilege to read this excellent atlas illustrating the value of cardiac catheterization in congenital heart disease. Part I, which is concerned with technique, describes the equipment required, the procedure, and the complications. Most of the possible positions of the catheter are shown, with graphs recording direct measurements of systolic and diastolic pressures within the various chambers of the heart. Formulae for working out the various shunts are given. Part II describes in detail 17 interesting examples of congenital heart disease investigated by catheterization.

It is fitting that the first book on the subject should be written by Cournand and his colleagues, who have been primarily responsible for developing the technique in the United States. The data offered should prove valuable to all workers in this field. A minor criticism is the lack of adequate electrocardiograms, only standard leads being shown. It is hard to believe that the catheter has passed through the tricuspid valve and through a ventricular septal defect in Fig. 12, the appearances being indistinguishable from those seen when the catheter has penetrated an atrial septal defect or foramen ovale and mitral valve. Again, it is odd that Case 2, said to be an example of idiopathic dilatation of the pulmonary artery, should have right bundle-branch block. More might have been written about the many technical difficulties it is possible to encounter during passage of the catheter, and how they may be overcome.

The illustrations are good, the diagrams are exceptionally clear, and the text is simple and concise. The authors are to be congratulated on an opportune and most helpful contribution to cardiology.

PAUL WOOD.

PRACTICAL PHYSIOLOGY

Human Physiology. By C. G. Douglas, D.M., F.R.S., and the late J. G. Priestley, D.M. Third edition. (Pp. 258. 18s.) Oxford: At the Clarendon Press. London: Geoffrey Cumberlege. 1948.

The first edition of this book appeared in 1927; owing to Dr. Priestley's death in 1941 Professor Douglas alone has been responsible for the present edition. As is well known, the work is based on the practical course in human physiology given in the Final Honour School of Physiology in Oxford. The exercises described deal with respiration, respiratory exchange and energy production, blood cells, plasma constituents, blood gases, certain aspects of the circulation, secretion of urine, and the examination of the alimentary canal in man. The instructions for carrying out the experiments are clear and detailed, and where necessary the calculation of arithmetical results is illustrated by examples. The new edition has been subjected to a careful revision, based partly on teaching experience and partly on the introduction of improved methods of investigation. Some interesting new experiments have been added.

The book is a model of its kind. It fulfils Professor Douglas's hope that "it will encourage the student in careful observation and accurate experimental work and afford him an introduction to the methods by which our knowledge of human physiology is being steadily increased." In many of the exercises the student is repeating the classical experiments by which the Oxford School of Haldane, Douglas, and Priestley established the fundamental facts about the control of many bodily functions in man.

The significance of the experiments is discussed at length. There is often a danger that a student might regard his practical work as a set of complicated parlour tricks which he must master to please his teachers and satisfy his examiners, but any student working conscientiously through this book will soon see that he is demonstrating for himself the truth of the principal affirmations made in his

textbooks, and that "theoretical" physiology is based on observation, experiment, and careful reasoning. Professor Pickering recently emphasized in the *Journal* the central place of physiology in the medical curriculum and the value of good practical courses on man in teaching the scientific method and outlook. Professor Douglas's book has for a generation been a major factor in helping to produce men capable of doing sound research; the new edition will be widely welcomed by teachers of physiology who have long recognized their indebtedness to this volume in planning their practical courses for medical and science students.

SAMSON WRIGHT.

A FRENCH MONOGRAPH

Physiologie du Système Nerveux Central. By G. Morin, Professeur de Physiologie à la Faculté de Medecine d'Aix-Marseille. (Pp. 270; 69 figures. 950 francs.) Paris: Masson.

This little book on the physiology of the central nervous system is attractive and useful. The subject has been treated in a novel manner which represents a physiological standpoint. The work starts with a consideration of the spinal roots and an outline of the autonomic system. The spinal cord is discussed as an organ of conduction and as a reflex centre: in the latter section the Sherringtonian principles of reflex action are introduced. The next chapters deal with muscular tonus and equilibration, the cerebellum, the cerebral cortex, the thalamus, the hypothalamus and the basal ganglia.

The diagrams are clear and the subject matter is up-to-date and logical. Such topics as the suppressor strips, the extrapyramidal tracts, and electroencephalography are described in reasonable proportion to the older matter. The author is non-committal regarding the location of the cortical area for taste, but inclines to the recent view that it is situated in the somatic face area. Two minor misprints may be pointed out: in Fig. 11 (p. 27) the indications of the crossed and direct pyramidal tracts have been transposed, and on p. 226 the words "shame rage" are given for "sham rage," possibly on account of the statement that this is "tantôt de type sexuel."

C. LOVATT EVANS.

Dr. Thomas Bedford's *Basic Principles of Ventilation and Heating* (pp. 401; 123 illustrations; 25s.; London: H. K. Lewis, 1948) is to a considerable extent based on the investigations made during the last thirty years by the author and his colleagues on behalf of the Industrial Health Research Board. Two of the earlier chapters describe the methods and apparatus used for measuring thermal environment. The chapter on warmth and comfort describes the opinions of 2,000 industrial workers employed under different atmospheric conditions, and the sections on ventilation describe in detail the measurement of natural air flow in dwellings and factories. There are several chapters describing the methods employed for warming houses and factories, and an excellent article on work at high temperatures. The book is well illustrated and has a good bibliography and index.

In *Sex in Social Life* (edited by Sybil Neville-Rolfe, O.B.E.; foreword by Sir Cyril Norwood; pp. 506; illustrated; £1 1s.; London: George Allen and Unwin, 1949), Drs. Waddington and Marshall have contributed chapters on the biology of sex and the physiology of reproduction, Professor A. E. Heath writes on psychology and sex, and Dr. Forbes on sex and the family in primitive society. These four provide an admirable scientific introduction. The sociologists who follow are on less established ground, and much of what they write is open to legitimate criticism. The reader will find sensible discussions on topics including sex education, family planning, sex in middle age, and prostitution. This book contains wisdom and practical guidance for dealing with many of the sexual problems in the life of the community.

BOOKS RECEIVED

[Review is not precluded by notice here of books recently received]

An Epitome of the Laboratory Diagnosis and Treatment of Tropical Diseases. By H. M. Shelley, M.R.C.P., D.T.M.&H. 2nd ed. (Pp. 147. 10s. 6d.) London: Staples Press. 1949.

The Group Approach to Leadership-Testing. By H. Harris, M.D. Foreword by General Sir Ronald Adam, Bt., G.C.B., D.S.O. (Pp. 288. 21s.) London: Routledge and Kegan Paul. 1949.

A Textbook of Bacteriology. By R. W Fairbrother, M.D., F.R.C.P. 6th ed. (Pp. 484. 20s.) London: William Heinemann. 1949.

ALCOHOL AND CIRRHOSIS OF THE LIVER

The theory, first suggested in this country by Addison[1] *in 1836, that hepatic cirrhosis and alcoholism are aetiologically* associated has for over one hundred years defied all attempts at proof or complete refutation. That alcohol is not the sole cause of cirrhosis was readily established by the occurrence of the condition in life-time teetotallers and in peoples and races who abstain from alcohol on religious or other grounds. Nevertheless many studies in Europe and America have pointed to an undoubted relationship between alcoholism and cirrhosis. Some animal experiments in the past have failed to reveal any unequivocal toxic effect of alcohol on the liver, though Opie's experiments indicated that the effect of combining bacterial infection with toxic agents was greatly to enhance toxicity. In the majority of experiments in which alcohol appeared to have a hepatotoxic action the result was not necrosis or fibrosis but only a fatty infiltration. In human cases, too, acute alcoholism was recognized as a cause of severe fatty infiltration, and as long ago as 1870 Trousseau[2] drew attention to fatty infiltration as a precursor of Laennec's cirrhosis and as a frequent finding in the early stages of cirrhosis itself. It is only in the last few years, however, that the significance of fatty infiltration in the genesis of cirrhosis has been appreciated. Moreover, although in well-nourished animals the liver fat can be increased by administering a variety of toxic substances, the degree of infiltration, with the exception of that caused by phosphorus, is comparatively slight and can rarely be made to exceed 15% of the wet weight. On the other hand, fatty infiltration causing gains in weight approaching 50% of the wet weight can be readily induced in animals by maintaining them on suitable diets.

The relation of diet to the fat content of the liver has been closely studied by Best and his collaborators[3] in Toronto and Channon in Liverpool. As a result of their work and that of others it became possible to classify dietary factors into lipotropic and alipotropic, the latter enhancing the deposition of fat in the liver and the former preventing it or facilitating its removal when present. Most important of the lipotropic agents is choline, the trimethylhydroxy derivative of ethanolamine. Methionine, one of the "essential" amino-acids, is also actively lipotropic by virtue of possessing a labile methyl group which can be utilized in the body for the synthesis of choline. The activity of choline is apparently due to its being required for the synthesis of the phospholipid lecithin, of which it is a part. Of the alipotropic agents cystine is the best known; it owes its activity, at least in part, to its stimulating effect on the growth of animals on low-protein diets. Both carbohydrate and fat are also alipotropic in that the greater the intake of these substances the more lipotropic factors are required to prevent an increase in the liver fat.

Connor,[4] who also drew attention once again to the stage of fatty infiltration in acute alcoholism, was the first to attribute aetiological importance to the fat in the subsequent development of fibrosis, his contention being that the distension of the liver cells caused interference with their blood supply and nutrition, with consequent injury and fibrosis. That fatty infiltration quite apart from alcoholism may lead to fibrosis, a necessary corollary of Connor's theory, was soon demonstrated, first in dogs submitted to pancreatectomy and maintained on insulin and later in otherwise normal dogs with livers made fatty by high fat diets. Meanwhile the discovery by Györgi and Goldblatt[5] that extensive necrosis of liver tissue could be a consequence of nutritional defects had tended to obscure the precise relationship between fatty infiltration and hepatic cirrhosis. This became clarified, however, when Himsworth and Glynn[6] were able to show that nutritional deficiency could cause two quite distinct hepatic lesions in the rat—namely, massive necrosis and its sequel, post-necrotic scarring with nodular hyperplasia, resulting from the amino-acid deficiency; and fatty infiltration with its sequel—diffuse fibrosis (Laennec's cirrhosis) resulting from deficiency of lipotropic factors.

Animal experiments had therefore indicated that fatty infiltration was a stage in the development of cirrhosis, and that both alcoholism and nutritional deficiency caused fatty infiltration and were both to that extent cirrhogenic. The problem that remained to be answered was whether the fatty infiltration due to alcoholism was a result of a direct toxic action or merely the result of an associated nutritional deficiency which itself was the consequence of loss of appetite, gastritis, and poverty—common accompaniments of alcoholism. That the latter is the case is now shown by Best and

his colleagues, who describe the results of their experiments in the opening pages of this issue. Rats were maintained on a synthetic diet "as nearly adequate as possible with respect to all dietary components except the lipotropic factors." The latter were restricted to an extent which allowed the fat content of the liver to rise on average to 10%. Feeding alcohol to rats maintained on such a diet caused a reduction in appetite and hence a fall in calorie intake; this was partly compensated for by the calorie value of the alcohol itself. The average fat content in the livers of these animals rose to 20%, and in half of the animals fibrosis indicative of commencing cirrhosis was apparent. In "pair-fed" animals whose diets provided no additional calories comparable to those obtained from the alcohol no increase in fat or fibrous tissue was observed. When, however, the additional calories provided in the experimental group by the alcohol were provided in the control group by a supplement of sucrose, the results in the two groups were indistinguishable. Moreover in both groups the lesions were entirely prevented by increasing the intake of lipotropic agents either as choline, methionine, or casein. Thus so far as the liver is concerned alcohol is no more toxic than sugar, the deleterious effect of both resulting from an increased need for lipotropic agents in the diet. This well-conceived experiment thus answers the old question, Is alcohol toxic to the liver? The answer is, No; but a qualified affirmative could be given if it is explained that alcohol is only as toxic as a quantity of cane sugar of the same calorie value.

The implications of this not unexpected answer are important. It is imperative to ascertain whether the is typical of mammals in general in the response of liver to alcohol and whether human beings behave in similar fashion. It is also important to determine how much fat the liver can tolerate and for how long a core fibrosis supervenes. Glynn, Himsworth, and Sandan[1] have recently shown that the critical stage is reached when the fat in the liver amounts to 15%; above this the rate at which fibrosis appears is proportional to the fat content. If the human liver behaves like that of the rat—and the indications are that it does[2]—the supplementation of all alcoholic liquors with a lipotropic agent such as choline should prevent that fatty infiltration which is apparently the indispensable precursor of so-called alcoholic cirrhosis. As Best suggests, this raises "scientific, moral, financial, and gustatory problems." Nevertheless the incidence of alcoholism in the United States may well warrant such an experiment there. In this country, at least for some years to come, our livers are more likely to suffer from primary dietetic deficiency of lipotropic agents than from deficiency due to an excess of saccharine or spirituous liquors.

GENERAL PRACTITIONERS AND HOSPITALS

State schemes are often justified by their supporters on the grounds that they co-ordinate services and thereby make them more efficient, yet in this respect the Health Service has failed, creating divisions where none existed before. The Minister of Health has recently shown that he is aware of the unfortunate inclination of some regional boards to expand the hospital service at the expense of the general practitioner service by excluding general practitioners from hospitals at which they treated their patients and staffing these hospitals with whole-time specialists. He has made it plain in a recent circular[1] that regional boards are not to dispossess general practitioners, and their patients, of "cottage" hospitals, to which, in the words of the circular, "general practitioners of the neighbourhood can admit patients who require treatment within the scope of a general practitioner but who, for various good reasons, cannot be treated at home." There is probably a good case for expanding the consultant services; there is none for impeding the general practitioner from ready access to hospital work. At the Annual Representative Meeting this year representatives drew attention to the problem and protested[2] against the steady exclusion of general practitioners from work in hospitals, and the Conference of Local Medical Committees, as we report in the *Supplement* this week, returned to the subject on October 27.

While regarding as sound the Minister's advice on the importance of maintaining cottage hospitals, the Conference agreed that local medical committees must watch vigilantly to ensure that his intentions are carried out. The powers delegated to regional boards give them an independence, an ability to respond to local needs, which is essential if the day-to-day administration of the Service is not to become a crossword puzzle to be solved in Whitehall. But the Minister is ultimately responsible for their activities; indeed, under Section 6 (4) of the Act he is bound in using hospitals transferred to him by the Act "so far as practicable" to "secure that the objects for which they were used immediately before the appointed day are not prejudiced by the transfer." If evidence is brought to his notice that a regional board proposes to deprive general practitioners of access to a cottage hospital he will no doubt see that his policy is enforced.

Many speakers at the recent assembly of the WMA commented on the diminishing status of the general practitioner. Yet, as Dr. Fishbein pointed out, advances in therapeutics have greatly extended the general practitioner's opportunities to treat patients at home or in

[1] *British Medical Journal Supplement*, October 15, p. 168.
[2] Ibid., July 2, p. 1.

a cottage hospital. Refinement of therapy has brought new problems in diagnosis, and special tests that can be carried out only in a hospital or laboratory are often necessary to solve them. If the general practitioner is to make full use of modern drugs he must have access to the departments, particularly pathology and *x*-ray departments, where these investigations can be carried out. There are many occasions when reference to a consultant is unnecessary and time-wasting. Provided the facilities exist they should be available equally to consultants and general practitioners, and direct access is being granted to an increasing number of pathology departments. Consultants would probably welcome such an arrangement, for it should leave them free to play their proper part—that is, as consultants on difficult cases—and relieve them of work for which their special knowledge is not required.

If the great majority of labours are to be conducted by general practitioners and midwives, as they should be, hospital beds must be available to which women can be admitted and there delivered by the general practitioners themselves. This is more necessary now that many women are confined at hospital merely for social or economic reasons. In some places regional boards are said to have taken over a small hospital at which general practitioners formerly delivered their own patients, staffed it with whole-time obstetricians, and denied the general practitioners entry. Such fragmentation of the Health Service is to be deplored, for not only is it upsetting to the patient but it removes from the practitioner's care cases well within his ability.

With the knowledge that most medical students will become general practitioners the schools train them in clinical medicine, and it is a reasonable assumption that a general practitioner ought to be first and foremost a good clinician. When he finds that the trend in general practice is to impede him from exercising his clinical abilities the doctor is apt to be disconcerted, on complaining of this, to be told that general practice offers unrivalled opportunities for the prevention of neurosis or the practice of social medicine. Yet if general practitioners are to remain clinicians they must be closely linked with hospitals, enjoy ready access to their departments, and communication with their staff. There must be opportunity for the keen man to have charge of hospital beds as well as home beds, and he should be welcomed as a colleague who can supply useful information at the out-patient or *x*-ray department rather than looked at askance as an intruder. The Association has two committees studying the problem—one on general-practitioner specialists and the other on general practitioners as such in charge of hospital beds. They will have an important contribution to make to the smooth running of the Health Service and the maintenance of general practice as an interesting and honoured branch of medicine. Meanwhile it is up to general practitioners and their local representatives to ensure that the ground is not cut away from them by regional hospital boards in opposition to the Minister's intentions.

REHABILITATION OF THE TUBERCULOUS

During the war the prevention and limitation of illness and disability were matters of urgent national importance. Two ministries were active in helping persons out of work through physical disablement—the Ministry of Health, responsible through the hospitals for medical treatment and medical rehabilitation: and the Ministry of Labour, responsible for resettlement in suitable work and for vocational guidance and training. Rehabilitation and resettlement of the tuberculous should be an important part of the national effort to prevent the spread of tuberculosis and to help individuals to make a more lasting recovery as well as some contribution to production. But three factors at the present time hinder progress. The morbidity rate in England and Wales is slightly on the increase, and more so in Scotland, though indeed mass *x*-ray surveys and other improvements in diagnosis and case-finding may be partly responsible for this; hospital and sanatorium beds are far short of the number required for institutional treatment, which for most patients is the necessary first stage of rehabilitation; and there are too few houses available for tuberculous families. In spite, therefore, of the declared aim of the National Health Service Act to improve the speed at which patients are brought back to health and thereafter to work and of the opportunities provided by the Disabled Persons (Employment) Act, 1944, the number of tuberculous persons needing treatment and rehabilitation (believed to be some 30,000) tends to grow larger year by year. Elsewhere in this issue Dr. Frederick Heaf, writing from first-hand experience, discusses this problem and brings out four points of primary importance. First, it is impossible to be sure that a tuberculous person has completely recovered from his disability; secondly, there are no means of assessing a tuberculous person's capacity for work except by trial and error; thirdly, when the disease is active it is usually infective; and fourthly, the problems of financing rehabilitation and resettlement have not been effectively solved.

Patients notified as suffering from pulmonary tuberculosis fall into two groups: those who remain under observation for active disease, and those who are eventually classed as "recovered"—i.e., the disease has remained "quiescent" for two years and "arrested" for a further three years. An investigation in Lancashire[1]

[1] *Prevention and Treatment of Tuberculosis in the Administrative County of Lancaster*, 1945, T. Snape & Co., Preston.
[2] *Tubercle*, 1949, 30, 74.
[3] *Lancet*, 1949, 1, 563.

showed that out of all the patients diagnosed during any one year as suffering from pulmonary tuberculosis—with sputum positive, negative, or absent—70% receive institutional treatment, and some 60% will have died from tuberculosis during the following five years. Disquieting facts have also come to light about the patients classed as "recovered." Tattersall[2] found from a five-year follow-up of sputum-positive recovered cases that 10% of the patients deteriorated after an average period of six years as "recovered." It is such facts that have made many appreciate the advantages of the village settlement, with its post-sanatorium medical supervision and favourable living and working conditions. But only a very small number of places are available, and unfortunately there are many who cannot or who will not be admitted to these institutions. Perhaps in the future the rest, nourishment, regulated life, and medical supervision which these individuals require may be provided by the night sanatorium, with its 30–50 tuberculous persons fit for some industrial employment in special "Remploy" factories of the Disabled Persons Employment Corporation. In the assessment of a tuberculous person's capacity for work Grenville-Mathers[3] has recently devised a modification of the method which Brieger developed at Papworth. He uses a simple physical-efficiency index, but points out that it is mainly a guide for the non-medical officers of the Ministry of Labour. In fact he agrees with Heaf that "fitness for any occupation cannot be defined by physiological measurements alone."

The danger of infection from patients with active disease is of great consequence in industry. Heaf suggests that inherent resistance is the most important factor and that "after the primary infection has been overcome only large and repeated exogenous infections are of any danger." This, if true, has very important implications. It means that the tuberculous and non-tuberculous can be employed together—as is done successfully in some village settlements—provided the non-tuberculous have overcome their primary infection, are adequately nourished, and work under good hygienic conditions. But the difficulty of applying such conclusions, even if correct, is obvious. There is a great and increasing fear of tuberculosis among the general public, due on the one hand to propaganda about infection and on the other to the serious nature of the disease. Even if it is inherent resistance and not exogenous infection that matters after the primary infection has been overcome, fear of infection will long remain. The public should now be given information based on the most recent knowledge about the pathogenesis of the disease. According to Heaf the greatest difficulty of all in rehabilitation and resettlement is that of finance. No advances can be made if the tuberculous are employed without regard to their living conditions, but the maintenance of a high standard of living is expensive. Financial assistance is available, but the methods of obtaining it are confusing, for it is of one kind when the tuberculous person is a patient and another when he is being trained and prepared for re-employment. Only a few of the larger local authorities have so far accepted liability to maintain persons undergoing rehabilitation at industrial settlements as part of their obligations under Section 28 (2) of the National Health Service Act. Local authorities have here an opportunity to give a lead to the rest of the country, and it is to be hoped that they will not only be generous in giving financial help but will take active steps in other directions, such as by providing houses, to refit the tuberculous patient for life in the community.

BURNS AND BONFIRES

Each year the season of bonfires and fireworks brings to surgeries and hospitals patients with burns of all degrees and severities. Most of these accidents could be prevented if common-sense precautions were taken, but, however unnecessary the injuries may be, the doctor is presented with the problem of treating them. The three principles of the modern treatment of burns are fluid replacement, the prevention of sepsis, and skin grafting if the injury extends through the full thickness of the skin. Intravenous plasma or its equivalent is usually required for patients with burns of 15% or more of the body surface. The amount to be given varies with the individual case and should be regulated in the light of repeated haematocrit or haemoglobin readings.[1,2] The fresh burn is usually free from pathogenic infection; it is also an excellent culture medium, so that great care has to be taken to prevent access of organisms. The best first-aid treatment is therefore to apply a sterile or freshly laundered cloth. At the surgery full sterile precautions should be the rule, and operating theatre standards are required in hospital. Large burns are particularly vulnerable to air-borne infection, and therefore to give the patient the best chance dressings should be done in virtually bacteria-free air such as can be provided by air-conditioning. A good local application should be soothing and assist in the prevention and control of infection: a cream of penicillin in a "lanette wax" base, as recommended by Colebrook,[3] fulfils these requirements. It can be covered with gauze, outside which a liberal layer of cotton-wool provides a bacterial filter, equalizes pressure, and protects from further trauma. The pressure is best applied over the wool with crepe bandages, and the whole dressing should extend well above and below the injury. Such a dressing can usually remain in place up to 10 days. Should it become soaked with exudate it will cease to be an effective barrier against infection, and the dressing must be renewed.[4] Within seven to fourteen days

superficial burns will be healed, and those a little deeper but with surviving epidermal cells will show islets of new epithelium. Burns extending through the full thickness of the skin, on the other hand, will never heal satisfactorily from below, and once diagnosed should be grafted as soon as possible.[5] Split skin grafts suffice for most burns treated early, and late secondary repair should be required only exceptionally.

The burns which occur on Guy Fawkes night are notable because they should be easily avoided, but study of the far more numerous everyday burns and scalds discloses the same story. In their recent analysis of 1,000 consecutive admissions to hospital for the treatment of burns the Colebrooks[6] point out that most of these injuries were preventable, and that in particular more attention should be paid to the disastrous results of clothes catching fire. The medical profession, since it is aware of these facts, has a responsibility to make them known and so to prevent these injuries occurring.

EARLY DETECTION OF CANCER

The only hope at present of improving results in the treatment of malignant disease lies in earlier diagnosis. The problem is a difficult one, being largely a matter of educating the public to report the early symptoms. In order to make it easier for patients some hospitals have established cancer diagnosis clinics during the past few years, and in fact over five hundred such clinics already exist in the U.S.A. Haagenson[1] has recently pointed out that what the patient needs is more courage and less fear; he makes the important observation that the propagation of information by cancer societies tends to alarm the patient so much that he is afraid to seek advice.

There is as yet no simple test for establishing the presence of a malignant tumour, and radiological and histological methods must suffice in the majority of cases. Haagenson reviews the diagnostic problem for each of the most common types of cancer. His general conclusion is that cancer can be divided into two classes: accessible and inaccessible. Accessible neoplasms include those of the breast, cervix uteri, skin, prostate, rectum, lip, and mouth, while neoplasms of the stomach, colon, lung, pancreas, and ovary are in the inaccessible group. The importance of this differentiation, in Haagenson's view, is that any trained physician should be able to make the diagnosis in the first or accessible group with no more equipment than would be expected in the general practitioner's consulting-room. Diagnosis of the inaccessible types is a different matter, since elaborate apparatus and complex procedures may be required. This differentiation into accessible and inaccessible types is further considered in relation to the question of establishing universally available cancer detection clinics. Reports from existing American clinics do not indicate that they have had great success in the detection of the inaccessible types of cancer; this is partly because routine *x*-ray examinations, such as would be necessary for the early diagnosis of cancer of the stomach and colon, are too expensive to be practicable. Haagenson's conclusion is that responsibility for the early diagnosis of all disease, including cancer, must remain with the general practitioner, and that it is he who must put the patient on to the right road for investigation and treatment. Haagenson is against the formation of special cancer detection clinics; in his opinion the important thing is to concentrate on improving postgraduate education in the latest methods of diagnosis of cancer.

There are many who will not agree with Haagenson's views. Although the general practitioner is not likely to miss the most obvious of the accessible cancers, those of the female genital tract present a separate problem. Specialized gynaecological knowledge is needed for their early diagnosis, and certain of the recent diagnostic methods, such as the vaginal smear, require great experience of a difficult technique. Maliphant has discussed the incidence of cancer of the cervix in a paper published recently in this *Journal* (June 4, p. 978), and in his opinion the routine examination of the apparently healthy is the only method by which cases of the disease could be discovered at a very early stage. But according to his estimate only one cervical cancer would be found annually in every 1,500 women examined, even if these came only from the more vulnerable section of the community—parous women aged 35–64. MacFarlane, Sturgis, and Fetterman[2] have reported the results they obtained over a 10-year period in a clinic designed to provide regular pelvic examination of presumably well women with a view to detecting cancer of the uterus. In this period eight cases of pelvic cancer, four of them growths of the cervix, were discovered and treated. A large number of benign pelvic lesions were diagnosed, many of them being inflammatory lesions of the cervix, the treatment of which, the authors believe, may be of great importance in preventing the subsequent development of cancer. They conclude that the greatest value of this work has been educational, in that a thousand women and their relatives and friends have been taught the value of periodic pelvic examination, and they suggest that every woman over the age of 30 who has borne a child should be examined once or twice a year if inflammatory lesions of the cervix are present.

POISONING BY FERROUS SULPHATE

The corrosive action of ferrous sulphate is largely dependent on its acidity. This may be countered by mixing with alkali in the proportion to form ferrous carbonate, or mineral acid may be avoided by the use of ferrous ammonium citrate. However, the absorption of iron from these two preparations leaves something to be desired, and it is a common practice at present to give iron as ferrous sulphate mixed with a small proportion of copper sulphate and manganous sulphate: the pill is coated with sugar and dyed green. This pill, which commonly contains ferrous sulphate gr. 3 (200 mg.), copper sulphate gr. 1/25 (2.5 mg.), manganese sulphate gr. 1/25, is widely used and causes no ill-effects in the majority of adults. It is not surprising, however, that young children should be attracted by such pills and take them in quantity when they have the opportunity. In this issue Dr. J. H. Prain (p. 1019) describes yet another case of fatal poisoning by these iron pills and refers to previous publications in this *Journal* by Thomson[1] and Forbes.[2]

[1] *Bull. N.Y. Acad. Med.*, 1948, 24, 651.
[2] *J. Amer. med. Ass.*, 1948, 138, 943.

[1] *British Medical Journal*, 1947, 1, 640.
[2] Ibid., 1947, 1, 367.
[3] Ibid., 1947, 2, 201.

Five cases of poisoning have so far been recorded; in only one of these, that of a boy of 2 years who retained eight tablets, was there recovery. All these cases occurred in Scotland and the northern half of England, and it is likely that there have been other cases in this country which have not been reported. In the fatal cases the number of tablets taken was about thirty, and the ages of the children ranged from 11 months to 3 years and 3 months. Corrosive action on the stomach was observed in all the cases, the duodenum and small intestine being less affected. Prain found definite necrosis and fatty changes in the liver in his case and suggests that absorption of the iron may have taken place largely through the damaged stomach wall. Forbes demonstrated on animals that the toxic agent is ferrous sulphate and that the copper sulphate is present in too small a proportion to have appreciable toxic effect. Somers[3] has demonstrated that the acidity of the ferrous sulphate is important, and he found that Blaud's pill was far less toxic in rabbits than the same dose of iron as ferrous sulphate. Both Prain and Forbes quite rightly suggest that more care should be taken in warning the patient that this preparation is dangerous to young children. Possibly accidents might be prevented if the pills were made in a form less attractive to the eye, but a child who will suck matches headed with red phosphorus would scarcely be deterred from taking the pills because they did not look attractive or taste evil at first.

THE PRE-ERYTHROCYTIC STAGES OF PLASMODIUM FALCIPARUM

Pre-erythrocytic cycles have for some time been recognized as occurring in the various species of plasmodia infecting birds. In 1948 Shortt and Garnham[1] showed conclusively that a pre-erythrocytic cycle existed also in the case of the monkey malaria parasite *Plasmodium cynomolgi*, which resembles very closely the human parasite of benign tertian malaria *P. vivax*. Shortly afterwards, in a paper which appeared in this *Journal*, Shortt, Garnham, Covell, and Shute[2] demonstrated the pre-erythrocytic stage of *P. vivax* in the liver of a human volunteer. In a third paper Shortt and Garnham[3] described further experiments with monkey malaria and gave their reasons for the assumption that after establishment of the blood infection the exo-erythrocytic cycle is responsible for the production of relapses. The persistence of these exo-erythrocytic forms in the human liver is presumably the cause of the relapses which occur in *P. vivax* infections. *P. falciparum*, the causal agent of malignant tertian malaria in man, differs in certain ways from *P. vivax*, and there is no known monkey plasmodium which can be used as a working model. For this reason an experiment in man was absolutely essential if the pre-erythrocytic cycle of *P. falciparum* was to be demonstrated. In the preliminary communication which we publish on page 1006 Colonel H. E. Shortt, Professor N. Hamilton Fairley, Sir Gordon Covell, Mr. P. G. Shute, and Dr P. C. C. Garnham have clearly demonstrated with the aid of a human volunteer, to whom they pay just tribute, the existence of a pre-erythrocytic stage of *P. falciparum* in the liver. The development of this previously unobserved form has been followed from 92 to 140 hours after infection. Although there are certain small differences in the appearance of the pre-erythrocytic stages of *P. falciparum*, *P. vivax*, and *P. cynomolgi*, all three parasites are closely related. It remains to be determined why *P. vivax* is so much more difficult to eradicate from the tissues than *P. falciparum*.

VITAMIN B_1 AND THE HEART

Cardiac irregularities associated with vitamin B_1 deficiency have been observed by several workers. In 1929 Carter and Drury[1] showed that the heart block occurring in pigeons fed on a diet of rice disappeared when atropine was injected or when the vagus nerves were cut. They concluded that the heart block was due to over-action of the vagal centres and not to any change in the heart itself. Wintrobe's[2] experiments in pigs had similar results. In eight out of nine pigs with thiamine deficiency the P-R interval was prolonged; two developed second-degree block and one complete heart block. Atropine caused the second-degree block to disappear in one pig and shortened the P-R interval in another. Thus in these pigs there was again evidence of excessive vagal activity. Other workers, however, have reported abnormalities in the heart itself: King and Sebrell[3] observed lesions, chiefly in the auricles, in 14 out of 24 rats. In pigs fed on a thiamine-deficient diet Follis and his colleagues[4] found dilatation of the heart and focal or diffuse necrosis of the myocardial fibres; again the early lesions were in the auricles. Pantridge,[5] who was led to the investigation after observing heart block in cases of beri-beri in British prisoners of war, has also demonstrated lesions of the auricle in pigs. Four animals deprived of thiamine developed heart block, and in two this was complete. Changes could be detected histologically in the auricular muscle and in the conducting system in the ventricles. Pantridge suggests that the metabolism of the auricular and ventricular myocardium must differ in some respects, and this is supported by the finding of Davies and Francis[6] that the distribution of glycogen, phosphocreatine, and adenosine compounds is very different in the two parts of the heart. Since gross deficiency of vitamin B_1 leads to pathological changes in the heart, possibly mild degrees of deficiency persisting over years may be a cause of similar abnormalities.

The Nobel Prize for Physiology and Medicine has been awarded jointly to Dr. Walter Rudolf Hess and Professor Antonio Egas Moniz. Dr. Hess has been Director of the Institute of Physiology at Zurich University for the past thirty years. Professor Egas Moniz, of Lisbon University, is a distinguished neurosurgeon and was at one time Portuguese Minister of Foreign Affairs. He introduced cerebral angiography in 1927 and the operation of prefrontal leucotomy in 1936.

Dr. J. G. Scadding, F.R.C.P., will deliver the Bradshaw Lecture before the Royal College of Physicians of London (Pall Mall East, S.W.) on Thursday, November 10, at 5 p.m. His subject is "Sarcoidosis, with Special Reference to Lung Changes."

REFRESHER COURSE FOR GENERAL PRACTITIONERS

THE USE AND ABUSE OF VITAMINS

BY

L. S. P. DAVIDSON, B.A., M.D., F.R.C.P.
Professor of Medicine, University of Edinburgh

During the past 40 years discoveries in medicine and related sciences have led to an immense improvement in the health, happiness, and efficiency of millions of human beings throughout the world. In no branch of science have more important advances been made than in nutrition. The fascinating story of the discovery of the vitamins, the dramatic changes produced by their deficiency, and the remarkable therapeutic effects which result when they are supplied to individuals who have been eating an inadequate diet have received great publicity in both lay and medical press. The imagination of all who have heard or read about these discoveries has been stimulated and captivated. It is not surprising therefore that there has arisen a demand for vitamin preparations which has led to their manufacture and distribution on an enormous scale. But there is little doubt that at present large quantities of these preparations are consumed by individuals who can expect to receive no benefit whatsoever from them, since they are not suffering from nutritional deficiencies. The medical schools of Great Britain must shoulder their share of responsibility for the continuation of this unsatisfactory state of affairs, since it indicates that many members of the medical profession must have received insufficient training as undergraduates or postgraduates in the science of nutrition. Better instruction is essential to enable doctors to assess properly the validity of the claims made for vitamin preparations in the advertisements with which they are daily bombarded, and to investigate adequately the dietetic history of patients they suspect of suffering from nutritional deficiency.

Confronted with a patient complaining of such symptoms as fatigue, lassitude, loss of appetite, irritability, or insomnia, which are repeatedly stressed in advertisements of vitamin preparations as being the stigmata of subclinical states of nutritional deficiency, there is danger of the doctor prescribing a vitamin preparation without first fully investigating the physical, social, and environmental factors that so commonly lead to similar subjective features.

General Considerations

(1) It should constantly be remembered that in Great Britain fully developed states of vitamin deficiency such as beriberi, scurvy, and pellagra are very rarely encountered. When they do occur they usually appear in individuals of a certain type—elderly persons, frequently males who live alone, and in people with abnormal mental states who are either unable or unwilling to eat a normal diet. They also arise as "conditioned" states of vitamin deficiency—as a result of gastro-intestinal disorders which lead to a failure in digestion and absorption, or from the increased demands which occur during pregnancy and lactation, rapid growth, or markedly increased metabolism.

(2) Food supplies at present available from rationed and unrationed sources in Great Britain are capable of supplying all nutritional demands, provided the individual has some knowledge of what constitutes a reasonably well balanced diet. This has been clearly established from our knowledge of the total supplies of food available for distribution, from studies of the consumption of food by large numbers of working-class families, and from public health statistics. The general practitioner, if adequately trained in the science of nutrition, is the proper person to give advice to the family on how to eat, when to eat, and what to eat.

(3) It is a well-established fact that, if an individual is eating a sufficiency of any vitamin, supplementation of the diet by a vitamin preparation will effect no benefit and is therefore wasteful and uneconomic.

(4) Although the dominant clinical features may suggest a deficiency of one particular vitamin, experience has shown that deficiency of a single nutritional factor is seldom present alone. Almost invariably the diet will be found to be lacking in several factors. The administration of a single or multiple vitamin preparation without correction of the diet as a whole will lead to little or no benefit. This finding has been noted by many observers, including myself. I found no beneficial effects from supplying a preparation of vitamin A and D to school-children whose diet was defective in several factors, including protein, minerals, and vitamins. The children were drawn from the poorer classes and were investigated during the years of depression between the two world wars. At about the same time in another region of Scotland, excellent effects on the health and growth of a similar group of children resulted from supplying them with a pint of milk daily. The psychological effects of giving vitamin preparations were clearly demonstrated in the former experiment, since many of the school teachers concerned in the experiment reported dramatic benefits in children whom they believed to be taking vitamins A and D but who were in fact being given an innocuous preparation of arachis oil in capsules identical with those containing the vitamins. This clearly indicates the need for caution on the part of a doctor in accepting subjective improvement after the administration of a vitamin preparation as being necessarily due to the correction of a state of pre-existing nutritional deficiency.

(5) Recent advances in knowledge call for a reconsideration of the generally accepted standards of vitamin requirements for the maintenance of health. The proof that many vitamins are manufactured in the alimentary tract by bacterial syntheses is a discovery of the greatest interest and importance which largely explains the variable incidence of vitamin-deficiency diseases in individuals ingesting a similar diet. This fact also explains the difficulty in deciding what values should be accepted as desirable for the maintenance of health.

Information derived from studies of human volunteers living on a diet almost completely devoid of vitamins A and C (see references to Table) clearly shows that many months must elapse before symptoms or signs develop, and that clinical features will disappear completely on supplementing the diet with amounts of vitamins considerably lower than those formerly accepted as necessary. These investigations strengthen the view that the food supply

TABLE

Vitamin	Recommended Daily Allowance	Therapeutic Dose	Foods of Special Value
Aneurin (vitamin B)	1–2 mg.	10–50 mg.	85% extraction wheat flour, oatmeal, peas and beans, eggs, meat and offal
Nicotinic acid	10–20 mg.	200–500 mg.	
Riboflavin	1–2 mg.	5–50 mg.	As above, and milk and cheese
Ascorbic acid (vitamin C)	30 mg.*	200–500 mg.	Fruits, esp. citrus, currants and berries; green vegetables, tomatoes, potatoes
Vitamin A	2,500 I.U.†	25,000–50,000 I.U.	Eggs, cheese, milk, butter, vitaminized margarine, liver, fatty fishes, green and yellow vegetables
Vitamin D	Adults: (?) 100 I.U.; infants, pre-school children, pregnant and lactating women: 400–800 I.U.	1,500 I.U. up to 100,000 I.U. in special cases	Eggs, milk, butter, vitaminized margarine, fatty fishes (Note the importance of sunshine in promoting the synthesis of vitamin D in the skin)

The following vitamins are not included in the Table because their place in human nutrition is not clearly established or because they are only used for the treatment of certain pathological states: Pyridoxin, pantothenic acid, biotin, para-aminobenzoic acid, folic acid, vitamin B_{12}, vitamin E, and vitamin K.

* A preliminary report by Vitamin C Subcommittee of the M.R.C. (*Lancet*, 1948, 1, 853).

† M.R.C. Special Report Series No. 264, 1949.

available to the people in Great Britain are more than adequate to meet the vitamin requirements of the population without supplementing them with vitamin preparations, provided a reasonably intelligent selection of the available foods is made.

Prescription of Vitamins

Vitamin preparations have been prescribed for:

(1) Supplementing the diet to make it optimal for growth and the maintenance of health.

(2) Treating so-called "subclinical" states of vitamin deficiency.

(3) Treating fully established "frank" vitamin-deficiency diseases.

Bearing in mind the general considerations discussed above, the practitioner should make the following investigations before prescribing vitamin supplements:

(1) Take a careful history and make a full physical examination to determine the presence or absence of subjective phenomena or objective signs indicating vitamin-deficiency states.

(2) Consider whether any clinical features discovered are due to emotional states or organic diseases which can produce symptoms and signs simulating closely those of subclinical and "frank" vitamin-deficiency states.

(3) Take a careful dietetic history to determine whether there is evidence to show that the patient has in fact been eating inadequate quantities of essential nutritional factors.

(4) If the clinical features are in keeping with the existence of a state of vitamin deficiency and yet the dietary history does not suggest it, a search should be made for causes which are known to enhance the requirements for vitamins—malabsorption from the intestinal tract, pregnancy and lactation, rapid growth, infections, and states of increased metabolism. If no positive evidence can be obtained that a direct or conditioned state of nutritional deficiency has preceded the onset of the clinical features under investigation, it is extremely unlikely that they are nutritional in origin and it is illogical to treat them with vitamin supplements. The case should be carefully reviewed with particular reference to the possibility of hidden organic disease and to the factors operating in the home and at work which lead to psychological symptoms simulating those of subclinical states of vitamin deficiency.

Vitamin Supplements

Vitamin supplements should therefore only be prescribed as follows.

(1) *For the Maintenance of Health.*—Since all the factors required for the maintenance of health can be obtained from the food supplies and the extra supplements available in Great Britain at the present time, there would appear to be no adequate reason for the widespread prescription of additional vitamin supplements. Common-sense instruction on what foods to eat regularly is all that is required. The Table indicates foods which are the main sources of the most important vitamins in human nutrition.

It should be remembered that the concentration of a vitamin in any article of food is not necessarily the main consideration. For example, watercress has a high content of ascorbic acid compared with potatoes, but, as most people eat no watercress or only a very small amount occasionally, the humble potato is a far more important source of the vitamin. Another point to remember is in connexion with the method and rate of extraction of flour from wheat now in operation in Great Britain. The present process has so greatly increased the consumption of the B vitamins as to have largely solved this particular nutritional problem which was of such great importance in pre-war days, when 70% extraction white flour was the main source of carbohydrate. During the war the importation of fats, fruits, and vegetables had to be greatly restricted, with the result that nutritional experts were gravely concerned about the possible development of disorders due to a deficiency of vitamins A and C. Fortunately no such development occurred. Since the end of the war, fruits, particularly citrus fruits, and green and yellow vegetables have been imported in large quantities. These foodstuffs are available to augment the intake of ascorbic acid and carotene during the winter and spring months when the home production of fruit and vegetables is at its lowest.

Feeding experiments in human volunteers suggest that the requirements of vitamins A and C for adequate nutrition have been overestimated in the past. Even the figure of 2,500 I.U. of vitamin A given in the Table is about twice the suggested minimum protective dose required by the average individual. Hence there is little doubt that all vitamin requirements can be adequately met at the present time from food supplies readily available.

If an individual is taking the following helpings of food it is difficult to believe that he could suffer from any vitamin deficiency.

(1) An average helping of meat, poultry, rabbit, offal, or fish daily.

(2) 1 to 1½ oz. (42.4 g.) of fat daily (butter, vitaminized margarine, or cooking fat).

(3) 1 egg or ½ oz. (14.1 g.) of cheese daily.

(4) ½–2 pints (0.28–1.1 litres) of milk daily (according to such factors as age or pregnancy).

(5) 1 large or 2 moderate helpings of green or yellow vegetables daily.

(6) 1 large or 2 moderate helpings of potatoes daily.

(7) 1 helping of fresh fruit twice or thrice weekly.

(8) As much bread, scones, and cakes made from 85% extraction flour as desired.

When an individual is submitted to nutritional stress vitamin preparations may justifiably be prescribed. Special provision has been made for these purposes in Great

Britain by the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council. Supplements of cod-liver oil and orange-juice and additional quantities of milk are provided for pregnant and lactating women, for infants, and for children too young for school. It is undoubtedly wise to give these supplements to children up to the age of 5, particularly in winter time, and to school-children who are growing too quickly or who have had severe febrile illnesses. For adults, vitamin supplements should be very rarely prescribed for the maintenance of health except when there exist the additional strains and stresses already mentioned which enhance the need for vitamins.

(2) *For the Treatment of Subclinical Vitamin Disorders.*—The diagnosis of states of subclinical deficiency of vitamins is based not on objective signs but on subjective features. Even with the help of laboratory tests which are not readily available to general practitioners (e.g., plasma determinations of vitamins and saturation tests), it is far from easy to be sure that the symptoms complained of are nutritional in origin. While some physicians think that subclinical deficiency states are extremely common in Great Britain at the present time, others hold there is little satisfactory evidence to justify this view. I believe that the frequency of such states has been much exaggerated. Monotony of the diet and the frustrations and restrictions accompanying post-war life in Great Britain probably account for most of the subjective features attributed to states of vitamin deficiency. If, however, after making the requisite investigations discussed above, the doctor concludes that there is a state of subclinical nutritional deficiency present, he should treat the deficiency by ensuring that the patient takes a properly balanced diet. If this is done there will be no need or justification for prescribing vitamin preparations except when there is clear evidence of the patient being submitted to one or more of the above nutritional stresses.

(3) *The Treatment of Established Vitamin-deficiency Diseases.*—As already mentioned, frank deficiency diseases such as scurvy, pellagra, and beriberi are rarely encountered in Great Britain at the present time. Careful investigation of any such case that may be encountered will almost invariably reveal multiple deficiencies of protein, minerals, and vitamins. Correct treatment accordingly demands that the diet as a whole should be carefully reviewed and made adequate in all respects. In addition, vitamin supplements should be given in the therapeutic doses shown in the Table until all symptoms and signs of deficiency have disappeared.

Conclusions

If the views expressed above are accepted, it follows that vitamin preparations should not be prescribed routinely for the maintenance of health or the treatment of subclinical states of vitamin deficiency; the best way of treating these conditions is by instructing the patient how to choose and prepare a well-balanced diet adequate in all nutritional factors. Supplements of vitamins are indicated only when causes are found to be operating which greatly increase nutritional requirements. Frank vitamin-deficiency diseases are rare in Great Britain; their treatment consists in correcting the diet in all respects and supplementing it with appropriate doses of vitamin preparations. Accordingly it is suggested that if more attention were given to the proper diagnosis of nutritional deficiency, to the taking of a careful dietetic history, and to the principles governing the prescription of vitamin preparations discussed above much unnecessary expenditure would be avoided. The discovery and elimination of social and environmental factors which lead to symptoms simulating those of subclinical states of vitamin deficiency will produce better and more permanent results than will be achieved psychologically by the administration of vitamin supplements to individuals who are not suffering from a nutritional deficiency.

A MEDICAL VIEW OF THE SOVIET UNION

BY

M. T. GILLIES, M.B., B.Chir.

A year's stay in Russia is small qualification for anyone to express views on the country, but the experience for a medical man is sufficiently unusual these days for a few brief and entirely superficial impressions to be worth recording. It should be added that these observations are the outcome of an Embassy appointment in Moscow and are made with a knowledge of the limitations of outlook and opportunity that such a post entails.

No remarks on Soviet standards of medicine can possibly be made without a thorough knowledge of, and free access to, their institutions and hospitals. Under existing conditions this was denied me. Hospitals could be visited in connexion with foreign patients, but such opportunities were infrequent and their scope limited. Persistent efforts were, in fact, made to visit officially one particular Russian medical man of eminence, all of which, however, were deftly parried by VOKS, the Soviet organization for promoting cultural relations with foreign countries. In view of the recent disappearance and strongly rumoured arrest of a Russian surgeon of international repute it would not have been prudent to pursue the matter or the man further.

As the home of the first system of socialized medicine, Russia has obvious interest for us while our own National H[ealth] Service is being established. There are certain differ[ences] A fundamental one is the absence in their system of the [general] practitioner. The smallest unit is the polyclinic, roughly [equiva]lent to a health centre, which has a regional or occ[upational] basis—that is to say, its clientele belong to a certai[n trade] or to a particular class of workers. Individual priva[te] tioners do exist, but their activities are limited by lack [of] to hospital accommodation and by strict limitation [of] power of certification. A recent change of poli[cy] organization of polyclinics is evident from the [following] paragraph from *Pravda* for January 6, 1949.

"By a decision of the Government, the Ministry of P[ublic] is now carrying out an important reform of medical se[rvice] population. The existing polyclinics and dispensari[es] merged with the hospitals and clinics. As a result of th[is] dispensary physicians have begun to work in the hosp[itals] and for their part tens of thousands of specialists in [the] have come to the reception rooms. This system i[s] improving the quality of medical services to the populati[on]

Thus it seems that the present Soviet trend [is] centralization or affiliation of all medical servic[es] sort of parent hospital, whereas we envisage with [the] up of health centres what will be to some extent th[e] tendency. Two other small points may be noted. [Spec]tacles and spectacles, let alone wigs, are not issued free, bu[t] charged is not high. Secondly, it is significant that [private] practice among dentists is very flourishing and, so far as one can tell from casual acquaintances, their services are widely used. Incidentally the inauguration of the Health Service in Britain was the occasion for a violent article in *Meditsinsky Rabotnik* under the heading "A new law, a fresh burden on the shoulders of the workers of Britain." The provisions of the Bill were completely ignored and the author, a doctor, expatiated instead on the inadequacy of the medical services in England and the low standard of living of the masses—quoting freely from the correspondence columns of the *B.M.J.*

On the purely domestic side of Embassy practice specialist opinions and hospital treatment were arranged through a special diplomatic polyclinic, designed exclusively for the use of the foreign community. This was the one place where consultations could be held and opinions on medical and other matters

...ially exchanged. The building was equipped with *x*-ray ... physiotherapeutic plant and was lavishly furnished with ...pets and brightly coloured awnings. Everybody there was ...ays most helpful and co-operative. A quaint feature of the ...em was the payment of a not inconsiderable fee, cash down ...dvance, on entering the establishment.

Moscow itself has a fleet of fast "emergency aid" cars which can be summoned by dialling a simple number on the telephone. They carry stretchers and attendants under the charge of a doctor and provide a prompt means of admission to hospital. Smaller cars, labelled "House Aid," are often to be seen on the streets and provide treatment at home for those too ill to visit the polyclinics.

The Aptecka, or State pharmacy, is a characteristic feature of the Soviet system. These are usually rather large shops, open all night, with a big dispensary and sometimes with a department where toilet preparations and drugs requiring no prescription can be bought. Sulphonamides in small quantities can be obtained in this section, as for instance in a popular official remedy for influenza compounded of hexamine and sulphanilamide (0.3 g.). Vitamin preparations such as rose hip syrup and cod-liver oil can also be obtained. The range of drugs available is naturally very much more limited than in this country and there are frequent shortages—for example, santonin, sulphadiazine, and nitroglycerin did not appear to be generally available, although santonin was being regularly prescribed for the large number of cases of roundworm infestation.

The normal procedure for a patient obtaining a medicine from one of these pharmacies is for him to queue up at the receiving counter where the girl in charge checks the prescription and assesses the price. He then joins the queue at the cash desk and pays the small sum required before proceeding ...other counter where he either receives the medicine or is Vit... what time to return for it. Drugs are dispensed in small (1) ...ies and prescriptions need to be repeated frequently, and the general, as a system of supplying physic to a large (2) Th...f people cheaply and quickly it seems to work quite deficienc...e principal shortcoming is that recorded by *Pravda* ...icle already quoted. "In certain chemists' shops one (3) Tre...tain even the simplest medicines and prescriptions in diseases, ...and by the population, although our industry has Bearing ...ortunity for satisfying the need for medicines."

above, the aspects of the public health system are of interest. res...gations be... and other intestinal infections are common in the mal... d the pharmacies display posters describing the part (1) Take...lies and dirt in the causation of these diseases and appe...examinations for their control. In some parts of Moscow Shut...ective phe...summer of 1948 there was a free house-to-house in th...deficiency ...of "phage" in tablet form to be taken as a prophy- and (2) Consi...h how frequently or systematically this was adminis- mal...due to em...not possible to say. The Russians have, of course, afte...produce sy...l studies of the commercial preparation of various cyti...subclinical... the dysenteries.

Th... (3) Tak...ortance of seeking prompt treatment for venereal hi... there is ... widely advertised in Russia as in many other been eat... These exhortations are reinforced by the law factors ... a criminal offence "wilfully" to transmit venereal ... to another person. The law also relieves casualty ...ficers of their traditional Saturday night trials with acute alcoholics. In Moscow the police provide "*veetresveetele punkts*," or "sobering institutions," where any clients found incapable or unconscious on the streets may be accommodated for the night and perhaps afforded suitable treatment. They are discharged next morning and charged 25 roubles (a fifth of an average week's wage) for their night's lodging. This would appear to be a useful amenity in a climate where the frost could speedily dispatch anyone who was drunk and sleeping in the open.

During the course of the year the Lysenko controversy came to a head. The main battle was, naturally, fought out by the biologists, but there were minor skirmishes in the medical world. The whole issue is quite incomprehensible without some conception of the general feeling of optimistic expectation about the future which is widespread in Russia to-day and not always so apparent in England. In an article in *Meditsinsky Rabotnik* on September 15 last a writer stated, "By common effort we must cleanse the field of Soviet Medicine of all idealistic and metaphysical weeds, so that we can move forward in seven-league boots and quickly solve the problem put before us by the great Stalin—not only to overtake but to surpass in the near future the scientific achievements abroad."

A young scientific worker would perhaps feel that he must temporarily suppress his doubts and critical faculties with regard to genetics as the price for belonging to and working for what he believes to be a greater movement. In other words, the material advancement of the people of Russia, and indirectly of the world, as he believes it, is more important than scientific truth. On the popular side there is no doubt that Lysenko has been most successfully "sold" to the Russian public. I attended a cinema performance once in which a news-reel depicting several public figures was being shown. No interest was evinced by the audience until Lysenko appeared on the screen. He was immediately recognized, and his name could be heard in approving whispers all over the hall.

The emphasis on patriotism has been most marked in Soviet films recently. The central theme of *Court of Honour* was the trial of a misguided Russian scientist who gave away the results of his work to a visiting American scientist, later unmasked as a secret service agent in disguise. During the course of this film someone remarks, "These Americans! Why, they even sell us a single dose of streptomycin for the same price as it takes to build a house!" (Streptomycin is presumably available for sale to the Soviet Union at the same rate as to other European countries.)

Academician Ivan Pavlov was another recent film, giving the story of his life and work and emphasizing that he placed his country above his work and his patriotism above world science. This film contains one amusing non-political scene at Cambridge as Pavlov receives an honorary degree from the chancellor. In the middle of this impressive spectacle a little woolly toy dog descends suspended on a string amidst shouts of "Hullo" from the playful undergraduates in the gallery. The great man grabs the dog good-humouredly and continues the ceremony with it tucked tightly under his arm.

In contrast to the lack of personal contact permitted one could, as a scientific worker, have access to one or two libraries and museums, notably the big Lenin Library in Moscow. This is a fine modern building embellished on the outside with busts commemorating, for example, Newton and Darwin. Quite a wide range of Russian and foreign literature, especially German, appeared to be available and could be consulted without difficulty. But this free use of a Russian institution was notable as an exception to the general restrictions, as the scantiness of this account shows.

INSTITUTE OF DISEASES OF THE CHEST

OPENING BY SIR JOHN ANDERSON

The opening of the new premises of the Institute of Diseases of the Chest (British Postgraduate Medical Federation), in the grounds of Brompton Hospital, Fulham Road, took place on October 26. Sir John Anderson, M.P., chairman of the Governing Body of the Federation, who performed the opening ceremony, said that no observant layman could fail to be profoundly impressed by the progress made in medicine during the past half-century. Medicine, a profession which had been carried on for hundreds of years on traditional and mainly practical lines, could now claim as never before the attributes of an exact science. If the public were to have, as it was entitled to have through the National Health Service, the full benefit of all the developments of scientific medicine, a great extension of facilities for higher medical education and research was clearly essential, and that was the significance of the new Institute.

Sir John Anderson went on to remind his audience that this was one of a number of specialist institutes in process of being

established under the aegis of the Federation. There was no room for doubt about the justification for including this kind of institute in its framework. Despite what had been done during the past 35 years, there was still a need for concentrated effort in the sphere of chest diseases, and the contribution which the Institute could make to the public good would be commensurate with that need. He added that the tradition firmly rooted at Brompton would provide a most favourable atmosphere for successful work.

Sir Robert Young explained that the Institute would serve two hospitals—namely, Brompton and the London Chest Hospital, institutions very similar in their aims and objects. It would promote collaboration, and would serve to make London with its wonderful material a focal point of teaching and research in diseases of the chest. He himself joined the staff of Brompton Hospital 54 years ago, and he recalled the pioneer work of the staff in those far-off days. Since the hospital opened in 1849 many methods of treatment had been examined and tried out, and knowledge had advanced by strides. Perhaps it was in the department of surgery that he had seen the greatest change. Now the staffs of the two hospitals were doing their utmost to train young surgeons in this branch of surgery. The Institute was yet another new venture which he felt to be full of promise.

Dr. A. Roodhouse Gloyne, consulting pathologist to the London Chest Hospital, said that these two hospitals came into existence a century ago very closely together—the London Chest Hospital in 1848 and Brompton in 1849, the latter founded by Thomas Bevill Peacock, who wrote a standard textbook on congenital heart disease and also investigated a form of silicosis in workers on millstones for grinding flour. A tribute was due to other physicians in those early days who came to a right conclusion on what would now be considered very inadequate data. The hospital was also interested in cardiology, and some great men in this field had been numbered among its physicians. As a medical school the London Chest Hospital, until the end of the first world war, was a rather fortuitous institution, graduates coming and going without very much organization.

In the development of the new Institute he hoped that the humanities would not be forgotten. As the staff grew alongside each other, co-operation would improve until the Institute became a complete unit. One of the things the Institute would do would be to advance the study of industrial lung disease; he hoped the heart would not be forgotten, and that in investigating disease in the periphery of the chest the pericardium would also receive attention. The Institute would also study carcinoma of the lung, the incidence of which seemed to be advancing.

Plans for the Institute

Sir Francis Fraser, director of the British Postgraduate Medical Federation, said that the first step in an exciting venture had now been completed. For many years the large general hospitals were used for undergraduate education, but the special hospitals which offered almost unrivalled opportunities for the advancement of knowledge and for postgraduate and advanced education were hardly used at all. Committees had discussed the various possibilities, and as a result the Postgraduate Medical School was established at Hammersmith, with university departments in general medicine, surgery, obstetrics, and pathology; but it was agreed that no attempt should be made to set up university departments in the special branches at Hammersmith, and that these should be based on special hospitals. The new Institute represented a further milestone in this progress. It would be some time before the staff was completed to the extent which would fulfil the hopes and aspirations of the previous speakers, but it was already being gathered together. Under the National Health Service the London Chest Hospital was joined with the Brompton Hospital for the purposes of providing clinical material and staff, and it was with every confidence they looked forward to the development of the Institute.

The Institute will be able to provide whole-time courses for three months for 12 students and part-time courses for twice as many. When it is fully equipped—which will probably not be for some time—it is expected that there will be facilities for up to 50 students at once. The accommodation, which is all on one floor, includes laboratories, a lecture theatre, *x*-ray and photographic departments, a library and reading-room, and a refectory. It is hoped to carry out "pure" research as well as the routine research work of the associated hospitals.

Reports of Societies

CORTISONE IN RHEUMATOID ARTHRITIS

A meeting of the Section of Physical Medicine of the Royal Society of Medicine was held on October 12, when Dr. OSWALD SAVAGE discussed the effects of cortisone in rheumatoid arthritis, and gave an account of his recent visit to the Mayo Clinic.

Dr. Savage said that with some 50 other physicians from various parts of the world he was privileged to see the work on cortisone which was being done on the other side of the Atlantic. He saw two cases before and after treatment, and he had no doubt about the remarkable changes effected by this drug in rheumatoid arthritis. As was to be expected with research teams headed by Dr. Philip Hench and Dr. Kendall, the work was most carefully checked and controlled. The patients were suffering from severe active rheumatoid arthritis, and the changes which were brought about almost within a matter of hours were astonishing. One woman aged 55 had suffered from rheumatoid arthritis for three years; she could hardly walk, and was so crippled that it took her more than two hours to do her hair in the morning, yet within two and a half days of the first administration she was completely free from pain and walked normally. She declared that she felt a sudden improvement nine hours after the first injection; it was as if a load had been taken off her limbs.

The history of the work which led up to this discovery was fascinating. During the war it was rumoured that German pilots were given injections of suprarenal extract to increase their fighting morale, and there was a good deal of support for the theory that such an extract might be of value in battle fatigue. The rumour added momentum to the work already proceeding in the States, where Hench had been studying the reversibility of rheumatoid arthritis, and, turning to biochemical considerations, had concluded that what he had called the anti-rheumatic substance *x* might be the suprarenal hormone.

To understand the work on cortisone the adrenal steroids must be studied. Work on adrenalectomized animals had resulted so far in the isolation of 28 adrenal steroids, but only six of these, which could be divided into three groups, were active. The group which was oxygenated at the eleventh position and called 11-oxysteroid was the one with which this work was particularly concerned. As the work progressed a number of compounds were evolved, of which the one called compound E was by far the most active in its effect on carbohydrate metabolism. Dr. Savage also touched on the work done on the adrenocorticotropic hormone (ACTH) and its effects.

Clinical Results

Clinical improvement after the injection of cortisone might begin within four hours and was usually sudden. The patients felt as if something had been "unlocked" and lost their stiffness. Joints which had been tender on pressure were no longer painful when pressure was applied, and the swelling also disappeared, though not as quickly as the pain. They experienced a remarkable euphoria, and afterwards usually fell into a sleep of exhaustion. They acquired enormous appetites and sometimes had to be dieted to prevent obesity. The dose, given intramuscularly, was 300 mg. on the first day and 100 mg. on the second. The dosage of the adrenocorticotropic hormone was 50 mg. three times a day on the first day and 25 mg. on the second day.

The side-effects had been rather overemphasized, but it was necessary to make them known in order to help to ensure that

'AVLON'

brand

PENICILLIN PREPARATIONS

LOZENGES OF PENICILLIN

Each lozenge contains 500 units either of the Calcium (B.P.) or Crystalline Potassium Salt of Penicillin. *In containers of* 20 *and* 500.

CRYSTALLINE PENICILLIN WITH 'SULPHAMEZATHINE' (STERILIZED)

Containing 5,000 units of Crystalline Potassium Penicillin per gramme. *In bottles of* 25 *grammes.*

CRYSTALLINE PENICILLIN WITH SULPHANILAMIDE (STERILIZED)

Containing 5,000 units of Crystalline Potassium Penicillin per gramme. *In bottles of* 25 *grammes.*

OINTMENT OF PENICILLIN, B.P.

Containing 500 units of the Calcium Salt of Penicillin per gramme. *In tubes of* 25 *grammes.*

PENICILLIN OINTMENT FOR THE EYE, B.P.

Containing 1,000 units of the Calcium Salt of Penicillin per gramme. *In tubes of* 5 *grammes.*

'AVLOPROCIL'

Brand of Procaine Penicillin G Oily injection, with 2 % aluminium stearate. *In vials of* 10 *c.c., singly and in boxes of* 5.

WILMSLOW, MANCHESTER

ICI

Ph.263

Heparin-Boots

INJECTION OF HEPARIN B.P.

the natural anticoagulant

HEPARIN *is the granular substance present in the mast cells in the walls of the vascular and reticulo-endothelial systems.*

HEPARIN is a powerful, non-toxic anticoagulant without cumulative effects, which can be safely administered in large doses.

It is the only safe anticoagulant for use outside hospital practice, and has been used extensively for the prophylaxis and treatment of thrombosis.

Injection of Heparin-Boots is a pyrogen-free sterile preparation derived from high purity HEPARIN of not less than 100 units per mgm. Available in 5 ml. rubber-capped Vials (1,000 and 5,000 I.U. per ml.).

Literature and further information gladly sent on request to the Medical Department,

'ABIDEC' Drops

Eight Important Vitamins in Aqueous Solution

'Abidec' Drops may be taken directly on the tongue or mixed with milk in the feeding bottle, or with other foods, without altering appreciably either taste or appearance.

DOSE: For infants: 5 minims (15 drops) daily; for older children: 10 minims (30 drops) daily. In 10 c.c. and 50 c.c. bottles.

Each 10 minims (30 drops) of Abidec Drops represent:

Vitamin A	5,000 International units	Vitamin B_2	0.4 mgm.
Vitamin D	1,000 International units	Vitamin B_6	0.5 mgm.
Vitamin B_1	1 mgm.	Pantothenic Acid	1 mgm.
		Nicotinamide	5 mgm.
		Vitamin C	25 mgm.

when this drug became available, it was used only under the most carefully controlled conditions in hospital. Much study remained to be done on these effects, some of which were due to pituitary upset and electrolyte imbalance. Severe vomiting was followed the use of adrenocorticotropic hormone.

Unfortunately, directly cortisone was stopped the symptoms returned and the sedimentation rate again rose. In the severe cases so far treated it looked as if treatment would have to be continued indefinitely. The number of cases treated at the Mayo Clinic up to June of this year was only 17, but some of them had been under treatment and control for as long as six months. The difficulties of the production of the substance were immense; 39 long and difficult chemical steps had to be taken before even a minute yield was obtained. There had been accounts of other substances which might yield cortisone, but these related at present only to the theoretical stage. But two main points of progress were demonstrated even before the drugs were available for general use. In the first place it had been shown for the first time that the progress of rheumatoid arthritis was reversible rapidly by a drug; it had been known to be reversible in pregnancy, in jaundice, and after operations, but here was a drug which brought about the same effect. In the second place, a yardstick had been furnished with which to evaluate treatment. There had been many forms of treatment which improved the patient up to a point, but here a dramatic and rapid improvement was effected. Those who had seen the cases were impressed by the effect as compared with anything they had seen before, and thus a criterion was afforded for the treatment of rheumatoid arthritis in general.

Work in this Country

Dr. RAYMOND GREENE said that the relation of the adrenal cortex to rheumatoid arthritis had been studied by a number of workers. His own interest in the subject began some 12 years ago, and, while Hench and his colleagues reached their fortunate guess by way of a study of reversibility in pregnancy and jaundice, he approached the problem by seeking the common factor in a number of distinct conditions often associated with the onset of the disease. The hypothalamic endocrine system appeared to be a connecting link, and within this system the adrenal cortex seemed the most likely element to explore. He at first concentrated his attention on the operation of whole adrenal extracts and of desoxycorticosterone acetate, all of which were found to be ineffective. These were now being studied exhaustively in the United States.

In November, 1946, the worst case of rheumatoid arthritis he had ever seen was admitted to the Metropolitan Hospital, apparently in a moribund condition. The patient was a man aged 28 who had developed a classical rheumatoid arthritis at the end of June of that year, and the infection had spread rapidly until all the joints were involved; there was a low intermittent fever. He was treated with massive doses of acetylsalicylic acid and penicillin without effect, and a course of gold treatment was also valueless. A rash, afterwards found to be pemphigus, gradually spread over his body. His condition rapidly deteriorated; and he became so emaciated that his appearance resembled that of the prisoners at Belsen. General methods for restoration were begun, and in addition an intravenous procaine drip was set up. A certain amount of improvement took place, the joints became less painful, and the pemphigus ceased to spread. Later, however, deterioration took place. By that time the speaker had obtained some corticotropic hormone, and intramuscular injections were given over a period of 18 days in March, 1947. Each dose was of only 2 or 3 mg., much less than the American dosage, and, presumably because of the smallness of the dose, the improvement was not as rapid as that obtained by the Mayo Clinic workers. The improvement was not maintained, and the procaine injections were restarted. From that time (May, 1947) improvement again took place and continued, though slowly. The skin condition was obstinate, but eventually disappeared. A urinary condition was investigated and found to be due to stones in the pelvis of the right kidney, but as there was infection in the left kidney it was decided to leave it alone, and the infection had since disappeared. The patient was discharged from hospital in December, 1947, and had remained well ever since.

This patient was demonstrated to the Section, and was able to run up to the platform. His hands were still badly deformed, but his joints were painless and he was earning his living as a weaver. He had had no treatment for nearly two years. The most likely explanation, said Dr. Raymond Greene, was that a spontaneous remission was due during 1947, but those who saw him on admission were convinced that he would not have lived to enjoy that remission had it not been for the treatment he had received. Dr. Greene also described a second case treated with anterior pituitary corticotropic hormone, with a successful result. During the last three years he had concentrated his attention on other methods of producing increased adrenocortical activity, using substances which had an inhibitory effect on histamine release, but he was not yet ready to make a statement. He said also that there was a *prima facie* case for the further investigation of the role of the spleen in rheumatic diseases; this was likely to be the organ through which cortisone and corticotropin possibly produced their effects.

Dr. MAX REISS said that Hempel and he were probably the first to use corticotropic hormone in the treatment of rheumatoid arthritis when, in 1942, experiments were carried out on a group of patients suffering from involutional melancholia. The most interesting effect was the skin change: from being dry and parchment-like, the skin felt softer and thicker; the hair regained its lustre, losing its dry, brittle quality. A considerably smaller dose was given to achieve these and other effects than was used by the American workers, and it was important to emphasize this because, assuming that the hormone could not be prepared synthetically, the American dose of 25 mg. could hardly be the treatment of the future, for all the pig pituitaries in the world would not be sufficient to treat a thousand patients regularly. The continuous use of such a high dose was likely to discourage treatment, and as the dose was higher than the quantity produced physiologically in the body it could not be called a physiological dose. The reactions were such that responsible physicians would have to consider whether they were to embark on a treatment which could produce diabetic changes, alterations in blood pressure, and so on.

In some further discussion the point was emphasized that Hench had not claimed cortisone as a cure but had reported his work only as an "investigative therapy."

INTEGRATION OF PREVENTIVE HEALTH SERVICES

A meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on October 21 was devoted to a discussion of the preventive health services. Dr. W. H. BRADLEY, the president, said he believed this was the first time in the history of the Section that the subject of discussion had been purely administrative.

N.H.S. in Northern Ireland

Dr. A. T. ELDER described the National Health Service arrangements in Northern Ireland, though he pointed out that what might be successful in such a relatively small community might not have the same success in a much larger population. He instanced a number of respects in which the Service had been integrated. The first was the operation of the school medical service by the Ministry of Health and Local Government instead of the Ministry of Education. The services transferred to the health authority included the ascertainment of physically handicapped children, the provision of medical inspection and treatment, and the cleanliness and disinfestation services. A consultant paediatric service was awaited. The administration of the school meals and milk service remained with the education authority. There was close liaison between medical officers of health and directors of education. The scheme had been expanding during the last two years, and so far there had been a happy and efficient service. At the

beginning of this year rheumatic fever was made a notifiable disease; this involved consultative clinics, follow-up, and aftercare. So far 103 notifications had been received.

Before 1948 the care of tuberculous persons was vested in local authorities. It was now the function of an autonomous body called the tuberculosis board. The appointment of tuberculosis specialists rested, after consultation with the board, with the hospitals authority. Deaths from tuberculosis had declined in recent years, though ascertainment figures had gone up—an indication of the efficiency of the new system. Northern Ireland had a system of intimation of cases of suspected tuberculosis; this meant no worry for the practitioner, who simply said to the patient, "You might have something wrong with your chest. Do you mind just having a check-up?" and referred him for examination. Four out of five cases intimated proved to have no tuberculosis at all, but those which were proved were far more than had been suspected before the scheme began.

Other examples of integration were the fusion of all central Government medical services in the one Health Ministry; the medical supervision of industrial health by the Ministry of Health and Local Government instead of by the Ministry of Labour; the supervision of mental health services by a special committee of the hospitals authority; and the unification of preventive medicine with general practitioner services through the general health services board.

Dr. Elder added that vaccination against smallpox was compulsory in Northern Ireland; there was no conscience clause. From 1920, when the Government of Northern Ireland was set up, to 1947 only two cases of smallpox had been notified, both of them imported, one from Canada in 1924, and the other from Scotland in 1942. The percentage vaccinated ranged in recent years from 69 to 80%. Prosecutions were occasionally instituted, and these were followed by a new spate of vaccinations. During the past 20 years there had been only one confirmed case of encephalitis following vaccination, and in that case the patient had been vaccinated with lymph which had not come from the usual source.

Midwifery Services

Dr. M. W. GEFFEN referred to the arrangements for midwifery services in England and Wales. It was the duty of the local health authority to ensure that an adequate number of midwives were practising in the area. Domiciliary and institutional midwifery could not be separated; many confinements started at home and ended in hospital, but the domiciliary midwives were under the local health authority while obstetric specialists were employed by the hospitals authority. He thought that the midwifery service of the future, if it was to be integrated, must be placed under the regional hospital boards and eventually in the hands of management committees.

One of the most interesting parts of the work of the medical officer of health was the care of the school-children within his district, but to-day specialists were appointed by the regional hospitals boards, and although the divisional medical officer did some ascertainment the case afterwards passed from his hands to county headquarters and he heard no more about it. That was not a good example of integrated health services. Much was heard also about decentralization and the utilization of the services of the district medical officer as an assistant county medical officer, but his experience was that the district medical officer was very much of an assistant and had, practically speaking, no free hand at all. There had been in this respect a levelling down rather than a levelling up.

Dr. Geffen also questioned whether it was really necessary to have set up hospital management committees throughout the country. Was there not some existing machinery whereby hospitals in small groups could have done the work without a new organization? In his view there was no reason why the public health committees of local authorities should not have been the hospital management committees. It would have been a fine piece of integration if the public health committee of the local authority could have been made responsible for a group of hospitals, with the medical officer of health as chief officer. The setting up of additional committees with additional officers, while all the time there were standing committees democratically appointed, with officers of experience ready to hand to integrate the hospitals with the environmental health services, seemed a wasteful policy.

The M.O.H. and General Practitioners

Dr. E. D. IRVINE (Dewsbury) said that the present phase was one of expansion; consolidation would come later. He disagreed with those who complained so bitterly about the division of responsibility between hospital boards and health authorities. Any integration of service depended much more upon good will than upon a tidy machine. Even the environmental health services were not administered in a tidy and simple fashion. His experience was that the greatest possible value attached to meetings between medical officers of health and general practitioners and consultants. As it was, the medical officer of health had no place on regional board committees: on hospital management committees he might or might not have a place. His membership of the local medical committee was most valuable. In his area the general practitioners had a most friendly and co-operative attitude to other branches of the Service, but he wished that local medical committees could be established in smaller areas than counties so that other medical officers of health besides those of counties and county boroughs might take a useful place on them. He believed in an all-purposes local health authority of moderate size in which social work could be linked up with environmental control.

Dr. BRADLEY, from the chair, said that he thought Dr. Irvine might take it for granted that it was the generally accepted principle of those concerned in central administration that plenty of flexibility at the periphery was desirable, and if people at the periphery looked for opportunities to employ that flexibility nobody was going to get in their way. They were now watching a great new Service developing. They did not expect it to move smoothly at once, but they did expect it to move in the right direction. He asked whether in Northern Ireland the intimations of suspected tuberculosis were compulsory and whether any provision was made for payment of the notifying practitioner.

Dr. ELDER replied that in Northern Ireland the intimation of cases of tuberculosis by practitioners was not paid for. By Act of Parliament practitioners were required to report to the authority any suspected case; there was a penalty under the Act, but it was not rigidly enforced, and indeed in practice the arrangement worked better than had been expected. Where they had expected 3,000 or 4,000 intimations they had had 10,000. In general in Northern Ireland they believed in as much devolution of responsibility as possible. A question had arisen about general practitioners acting as obstetricians in smaller hospitals. Eventually it had been agreed that certain hospitals of the cottage hospital type, set apart for normal midwifery, should continue to be served by general practitioners, subject, however, to two provisos: one, that the advice of a consultant obstetrician must be available for any complication, and the other, that the obstetrician should have the right to advise upon the competence of any general practitioner to do midwifery in these hospitals.

MANAGEMENT OF RHEUMATIC FEVER

A meeting of the Section of Medicine of the Royal Society of Medicine on October 25, Sir ADOLPHE ABRAHAMS presiding, was devoted to a symposium on the management of rheumatic fever and its early complications.

Dr. PAUL WOOD, like ensuing speakers, based his remarks on observations made at the Canadian Red Cross Memorial Hospital (Rheumatic Fever Unit) at Taplow. It was important, he said, in the management of rheumatic fever to detect the presence or absence of carditis. According to the literature the average proportion of cases in which carditis was present was 50%; in the cases at Taplow it was 72%, but these were selected cases. Eight main signs of carditis were: (1) significant mitral systolic murmur; (2) Carey Coombs sign; (3) new or transient aortic diastolic murmur; (4) cardiac enlargement; (5) pericarditis; (6) signs of heart failure; and two electro-

cardiographic signs: (7) prolongation of the P–R interval; and (8) the Q–Tc sign.

The mitral murmur was commonly long and loud. About 45% of cases with loud murmurs developed mitral stenosis as against 9% of those with soft murmurs. The Carey Coombs sign had been found in 58 of the 75 cases with myocarditis. The murmur was permanent in the majority of cases. It went on or was recurrent until mitral stenosis developed. Carey Coombs had been right in supposing it to be due to organic mitral changes. An aortic murmur was heard in 44 of the cases. In the ordinary case little evidence of cardiac enlargement was seen radiologically, though a spurious enlargement was often noted. The heart enlarged with fever at any time and became smaller as the fever disappeared. Enlargement when due to heart failure was, of course, reversible; if the patient's condition improved the heart would become quite small.

Pericarditis had been a source of great trouble. It was not known how to diagnose it with certainty. Only 25% of the cases had shown this condition. As for heart failure, they had been pleased, and perhaps surprised, to find that patients with right heart failure did not die suddenly, and thus it was permissible to make investigations, of which at first they were very chary. He did not want to stress the electrocardiographic signs too much. The prolongation of the P–R interval occurred only in about 10% of the group, but the Q–Tc sign was useful. Dr. Wood concluded with a reference to rest and exercise. Before the principle of rest was given up, it was for the people who pleaded for exercise to prove that it did no harm.

Home or Hospital

Dr. E. G. L. BYWATERS reproduced an American estimate of the relative costs of care of the rheumatic case:

Home care	$ 30–35 per month
Foster-home care	$ 45–50 per month
Convalescent home care ..	$120 per month
Hospital care	$400 per month

If the home was well-to-do and the family physician available, home care might be preferable, but in the majority of cases the patient was better in hospital, preferably with a school attached. It was desirable that only one hospital should take care of the child. The first thing was to make sure that the case was really one of acute rheumatism. In a case of early osteomyelitis of the knee or hip it was better to start treatment with large doses of penicillin, even if the case proved eventually not to be one of rheumatic fever.

Rheumatic fever was a self-limiting disease, and if the cardiac sequelae could be prevented it would be of no more importance than mumps. It was the general opinion that the heart would be damaged less if the demands made on it were cut down to basal requirements. The Taplow cases afforded no evidence in favour of early rising, but in Chicago the active life, including boating and swimming, had been advocated, the only criterion being that the E.S.R. should begin to show a definite fall. Accepting rest as the most important measure in the treatment of cardiac rheumatism, for how long should the rest continue? The speaker showed a complicated chart, including temperature, pulse, and many other records, from the study of which, he said, they might feel capable of arriving at a true judgment of the stage which the condition had reached and of the point at which the child should be allowed up. The sedimentation rate was one of the most useful criteria; at Taplow it was estimated weekly. Salicylates produced a fall in the rate, but this was capricious, and it was felt that attention should not be paid to the actual level of the sedimentation rate while the patient was being given salicylates. Weight changes, although slow, were reliable guides. Bed rest must be maintained, and then the patient should be got up gradually, a close watch being kept on all phases of his activity.

Salicylates, although they had been in use for three-quarters of a century, still provoked a great deal of argument. They were able to do little more than relieve symptoms. They depressed the sedimentation rate not only in rheumatic but in non-rheumatic subjects. He did not think they actually cured the disease.

Penicillin in Prophylaxis

Dr. J. A. PITT EVANS said that workers in America and Australia had found that small doses of sulphonamides had some prophylactic value, but sulphonamides given over a long period might have a deleterious effect. Penicillin, on the other hand, was practically devoid of toxicity. In the experiment he reported one daily dose of 100,000 units of penicillin in 5% glucose was given before breakfast. This study had been carried out from November, 1946, to September, 1948, and concerned 165 children, with a control group of 145. The details of the study will be published, but Dr. Pitt Evans said that the evidence appeared to show that penicillin was of considerable value in preventing streptococcal infections—and consequently rheumatic relapses—among children in a convalescent home.

Professor ROBERT CRUICKSHANK said that records of the previous five years had shown something like a 50% relapse rate, but in this experiment the control cases did not show the incidence one would expect. The fact was that when a prophylactic measure affecting half a community was introduced the load of infection was considerably reduced, and therefore the rate of clinical infection expected from previous records might not be attained. Nevertheless, even the statistician would be satisfied that the penicillin was of value, and he was sure it was a method of prophylaxis to be followed up.

In some further discussion Dr. T. F. COTTON said that the Government should be praised for what it had done in building up the national institution at Taplow. As for treatment, his experience led him to the conclusion that rest alone availed. Dr. JENNER HOSKIN said it had been interesting to learn of the importance of the loud systolic murmur which was often heard in elderly patients and to which not much attention was paid. The pulse rate was not entirely reliable, as it varied with the excitability of the child.

Social Factors

Dr. GERALD SLOT mentioned the change in the type of rheumatism seen to-day as compared with that seen not many years ago. In the early 'thirties and even later a common case of rheumatism seen at supervisory centres was the child with swollen joints, but this type of rheumatism did not seem to be as common as formerly. Dr. Slot also made some observations on the social class from which the majority of rheumatic children came. A social survey in West London showed a large number of patients coming, not from the poorest class, but from the lower middle classes. He had been in touch with the medical officers of some of the largest public schools, and they declared that this was not a problem which affected them at all, yet in the rheumatism supervisory centres organized by the L.C.C. there was an overflow of cases. A theory which he thought he could disprove was that rheumatism was associated with dampness. Among children living in poor houses in riverside districts in London, where there was a lot of damp, he had not found any unusual incidence of rheumatic cases, although, of course, the damp house also suggested general poverty and perhaps lack of supervision. He had also noticed that when the pains were only in the leg it was likely to be an orthopaedic problem, and when they were in both legs and arms there was more likely to be a rheumatic factor concerned. He did not find much help in the electrocardiogram; when help was most needed it was least helpful. The sedimentation rate was of value, though he thought that in their eagerness to get hold of any method of assessment they tended to rely on it rather too much. It was a non-specific test. He did not think that salicylates did any good beyond relieving pain.

The Third Congress of the International Scientific Film Association, which was recently held at Brussels, included fourteen delegates from Britain. The Royal Society of Medicine was among the bodies represented. The inaugural presentation of scientific films was attended by Her Majesty the Queen Mother of the Belgians, who later commented on the excellent quality of the British films shown. Information about the work of the Scientific Film Association of Great Britain may be obtained from its secretary at 4, Great Russell Street, London, W.C.1.

Correspondence

R.M.B.F. Christmas Appeal

SIR,—Extra comforts at Christmas time are a great help in time of need—the little extra coal, the urgently needed warm clothing, the wherewithal to provide a real Christmas dinner. I appeal to members of the medical profession to bring these comforts to their less fortunate professional brethren, or to their widows and children who are beneficiaries of the Royal Medical Benevolent Fund. Not only will gifts bring them comfort and cheer, but their hearts will be warmed by the kind thought for them.

I hope that all, whether subscribers to the fund or not, will send donations to provide this little extra cheer, and that those who are not subscribers will become regular supporters of the medical profession's own Benevolent Fund. Donations and subscriptions, marked "Christmas Gifts," should be sent to the Secretary of the Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15, and will be gratefully acknowledged.—I am, etc.,

WEBB-JOHNSON,
President,
Royal Medical Benevolent Fund.

Malignant Tertian Malaria

SIR,—Your correspondent, Dr. P. Ross (October 22, p. 930), makes some sweeping statements about the clinical manifestations of malignant tertian malaria. It would appear to me that the clinical descriptions of well-known and generally accepted *accès pernicieux* of this infection are thereby impugned.

Most practitioners, I think, with an extensive experience of the vagaries of this type of malaria will agree with Sir Gordon Covell (October 8, p. 773). His statements regarding the protean manifestations exhibited by *Plasmodium falciparum* tally with my own in European soldiers exposed to mass infection under war conditions. I am certain that some exceptions have to be made in tropical natives, who may exhibit various degrees of immunity to subtertian malaria. That such immunity exists is hardly open to doubt, but numerous observers have drawn attention to the fact that they, too, may succumb to cerebral or abdominal malaria on being exposed to a foreign strain of *P. falciparum*.

It has been my misfortune to witness errors of diagnosis on more than one occasion, and to have seen laparotomy performed on what Dr. Ross terms "typical cases" of subtertian malaria. It would ill become me were I not conscious that acute appendicitis may occur during the course of malaria, or that acute cholecystitis may be a sequel to it—not that surgical intervention may be indicated in these cases—whether malaria parasites are present in the blood or not. But to advise young practitioners going out to the Tropics to ignore the teaching of textbooks which are based upon long and hard-won experience of subtertian malaria in many lands and under many diverse conditions would be a betrayal of the truth. I would remind your correspondent that the chapter on malaria in *Manson's Tropical Diseases* was not composed in a day or even after a flitting wartime experience.—I am, etc.,

London, W 1. PHILIP MANSON-BAHR.

Infant Vaccination

SIR,—Dr. C. Killick Millard (October 22, p. 929) takes me to task for "begging the question" of infant vaccination in the concluding paragraph of an article I contributed to the *Monthly Bulletin of the Ministry of Health* (1949, 8, 204). Dr. Millard's dislike of infant vaccination is well known. Unfortunately the evidence on which his views are based, and also those of many who disagree with him, is frequently distorted by less critical persons who seek to discredit not only infant vaccination but all vaccination against smallpox and, incidentally, immunization against diphtheria as well. This accounts, I think, for much of the reticence which at first sight might appear to be "question begging" in the references to this subject in official and other publications.

In the article in question I did not attempt to discuss the pros and cons of infant vaccination, and most certainly did not intend to minimize its difficulties and dangers, of which I am well aware, as may be seen from an article on post-vaccinal encephalomyelitis to be found in an earlier number (1948, 7, 72) of the same journal.

During the last 18 months I have been able to meet doctors concerned with the control of smallpox in Holland, France, and other European countries as well as in the United States and Canada. All of them I found to be aiming, though with varying success, at a well-vaccinated child population as an important part of their own national defences against smallpox. I was therefore concerned in my recent article to set out in some detail the current position of infant vaccination in this country and to point out that by our apparent neglect of this procedure we were giving the impression abroad that we were not regarding protection against smallpox as a serious matter at the present time. I submit that the paragraph quoted from my article can and should be read in that sense.—I am, etc.,

E. T. CONYBEARE.

Post-operative Thrombosis

SIR,—In these days when there is a more widespread awareness of venous thrombosis many clinicians, feeling that the early signs of calf thrombosis are sometimes slight and equivocal, are anxious to find some simple laboratory test which will give them courage in diagnosis and guidance in treatment. I was greatly interested by Mr. G. W. Vause Greig's article (October 15, p. 845), because I feel sure that the paper of Cummine and Lyons[1] to which he refers has given rise to unjustifiable hopes of a simple diagnostic test for thrombosis.

While there is commonly a fall in the coagulation time during or immediately after operation, most investigators have found that at a later stage there are rarely any significant changes. This observation is valid whatever method is used for estimation of the clotting time. I recorded clotting times daily in the majority of cases in two general surgical wards for a period of three months in 1948, and I have never found this investigation of the slightest help in diagnosing post-operative thrombosis. In the several cases of undoubted thrombosis which occurred during this period the coagulation graph did not show any significant change. In the present state of our knowledge it would seem that it is only by careful observation of the temperature chart and meticulous examination of the patient's legs that an early diagnosis of thrombosis can be made; it is perhaps remarkable that this essential practice is not even mentioned in Cummine and Lyons's paper.

Our experience with the fibrinogen-B test has been similar to that of Mr. Vause Greig, but positive results were obtained in a smaller proportion of cases. The finding of fibrinogen-B has borne no consistent relationship to the occurrence of thrombosis, and it has also been noted that not all samples of β-naphthol are suitable for this test. My colleague, Dr. W. G. Dangerfield, has prepared his solution by the method of Lyons and has commonly found that it does not turn brown on exposure to oxygen. Under these circumstances gel formation does not occur. We cannot satisfactorily explain these results, although it may be that some preservative in the β-naphthol accounted for the failure of the test in many of our cases, since it was more often positive when older solutions were used.

The fibrinogen-B test, like the coagulation graph, is in my experience of no help to the clinician. There is as yet no test which will surely tell us which cases of thrombosis will advance and which will be spontaneously arrested. No test will relieve the clinician of the responsibility for careful daily observation of his patients, and in this he can be greatly assisted by residents, nurses, and physiotherapists who are constantly alert for the early signs of thrombosis.

FOR ORAL ADMINISTRATION

DERIVED FROM THE NATURAL OESTROGEN

EXTREME POTENCY MEANS

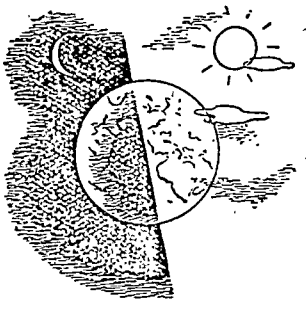
MINUTE DOSAGE WITHOUT SIDE EFFECTS

AT LOW TREATMENT COST

For all conditions where oral Œstrogen therapy Is indicated

Tablets of 0.01 mg. and 0.05 mg. (scored)

Tubes of 25. Bottles of 100 and 500.



Samples and full literature on request

The INEVITABLE *and the* AVOIDABLE

While recovery of the peptic ulcer patient may be jeopardized by frustration, fear and chronic emotional crisis, it should not be threatened by constipation so common to ordinary alumina gels. The former may be inevitable. The latter is fortunately avoidable, for Gelusil* Antacid Adsorbent tablets do not constipate as does ordinary alumina. Free from this distressing tendency—therapy with Gelusil need never be interrupted, nor demulcent protection suspended, nor relief withdrawn, nor healing deferred.

Each tablet—Mag. Trisil. 7½ grs.
Alum. Hydrox. gel 4 grs.

GELUSIL

'GENATOSAN'

COLOURLESS TAR CREAM

'Genatosan' Base 98.8%.
Pyridine 0.025%, Toluene
o-Cresol 0.05%, Carbazole
, Phenanthrene 0.20%,
e 0.025%, Xylene 0.05%,

'Genatosan' Dermatological Cream No. 19

Contains the active principles of coal tar in an emulsified ointment base, but is free from the irritant and inert substances which are present in black tar. The product is clean in use, will not cause irritation, and is particularly effective as an antipruritic and antiseptic. Indicated for pruritus, prurigo, neuro-dermatitis, lichenification, infantile and chronic eczema, psoriasis and for all other conditions where tar therapy is of value. Further information available on request.

1 *Brit. J. Surg.*, 1948, 35, 337.

SIR,—In his article on post-operative thrombosis Mr. G. W. Vause Greig (October 15, p. 845) suggests that a positive fibrinogen-B test in the post-operative period does not always predict that thrombosis will occur. Soon after operation I think this is true, and appreciation of this fact may prevent the indiscriminate prescribing of anticoagulant therapy based on a laboratory finding only.

In assessing whether a patient is a candidate for thrombosis one should always take into consideration age, previous history, and the results of careful clinical observation and examination. The use of anticoagulants in the post-operative period should not be undertaken lightly. When they are used too early there is the danger of severe wound haematomata. When used prophylactically they should not be administered before the third day following operation and the danger of wound haematomata should always be borne in mind.

Fibrinogen-B depends on the modification of fibrinogen by recently circulating thrombin in the blood stream. During and for some time after a surgical operation there must be some thromboplastin, liberated from tissue damage, which reacts with the prothrombin and calcium of the blood to produce thrombin. Therefore it is not surprising that following a surgical operation the plasma of the patient often gives a positive fibrinogen-B test. Since only a very small proportion of the patients develop a post-operative thrombosis, a positive fibrinogen-B test alone, soon after operation, is not sufficient evidence on which to predict whether a patient will develop a thrombosis.

Mr. Greig appears to have used the fibrinogen-B test described by Cummine and Lyons.[1] I had the pleasure of discussing with Dr. Lyons at Oxford last year the difficulties we were encountering with this test. He agreed with me that the original test did require some modifications. Since that time I have used with some slight modifications the test which he outlined as follows:

Nine parts of blood are mixed with one part of sodium oxalate solution (1.34%) and centrifugalized at about 3,500 r.p.m. for 10 minutes. The plasma is then removed and 0.5-ml. portions pipetted into each of three small tubes of 8 mm. internal diameter. To one tube seven drops, to the second six drops, and to the third five drops of the β-naphthol reagent are added from a Pasteur pipette. The tubes are gently shaken and allowed to stand at room temperature for 10 minutes, after which they are tilted and examined for gel formation. A positive result shows definite gel formation in one or more of the tubes. In the case of negative results the contents of the tubes are milky, but there is no sign of gel. If the tubes are centrifuged for one minute at about 2,500 r.p.m. and then reshaken the positive tubes show a definite coagulum, whereas the negative tubes show none or practically none, when tilted horizontally and viewed from above.

With regard to the value of the capillary-tube method for estimating whole blood coagulation time, it is now accepted as the least accurate of such methods.[2] Mr. Greig does not state at what temperature the clotting times were estimated. The variations in the temperature of the operating theatre and the wards at different times of the day could account for great variations in clotting time. There are of course other variables which affect this crude test. I therefore doubt whether the suggestion that "thrombosis, if it does occur, probably starts during or immediately after operation" can be confirmed by means of this test.—I am, etc.,

Manchester. H. LEMPERT.

SIR,—Although I am aware of the many difficulties inherent in conducting an investigation of intravascular thrombosis I feel that certain statements in Mr. G. W. Vause Greig's paper (October 15, p. 845) should not pass unchallenged. With regard to the method, Cummine and Lyons[1] estimated the coagulation time daily, and twice daily if there was pyrexia, and they stress the considerable group variation that may occur from day to day, and, contrasting it with the less common individual variation, they emphasize that it is only the persistently low or persistently falling clotting time that is of prognostic import.

When I had the opportunity a few months ago of discussing these tests with Lyons he again emphasized the importance of demonstrating this persistence, and pointed out that in his paper it was recommended that when the clotting time is below four minutes estimations should be made hourly during the following two hours; only if during these three consecutive hourly readings the clotting time remains persistently low should heparin be given.

Mr. Greig divides his results into four groups as suggested by Cummine and Lyons, but he is wrong in attributing to these authors the statement that it is only in Group 4 that there is danger of thrombosis. On the contrary, it is only Group 1 that is free from the danger. Patients in Group 2 are liable to thrombosis if they suffer from venous stasis or have had a previous thrombosis which can serve as a nucleus for further spread. Those in Group 3 have free thrombin in the circulation, and this has been seen as a primary phenomenon only after operation or parturition in the early stages before fibrinogen-B has had time to develop. It occurs usually as a secondary phenomenon following thrombosis and may then herald disaster, especially if the primary thrombosis has occurred in the pulmonary circulation. Patients in Groups 2 and 3 therefore require very careful observation both clinically and by laboratory investigation if thrombosis is to be prevented or diagnosed at its inception.

The one case in Mr. Greig's series which developed thrombosis would appear, in the absence of amplifying detail, to support the theory of Cummine and Lyons. The sequence of events shown on the chart suggests to me that this patient had, during her whole post-operative course, a tendency to thrombosis, that she, in fact, had a minimal thrombosis on the sixth day, and that the fall in clotting time which began on the tenth day was a warning signal to test again for fibrinogen-B. Whatever interpretation be placed on the events in this case it is clear that factors other than the clotting time in the presence of fibrinogen-B must be taken into account when considering, for example, intravascular thrombosis, venous stasis, tenderness in the calf, or pain on forced dorsiflexion of the foot.

One would have liked to see stated in Mr. Greig's paper the criteria on which he would base a diagnosis of thrombosis. His confirmation of the fall in clotting time occurring in most patients during and immediately after operation is in accord with the theory that the accelerated rate of clotting is due to circulating thrombin—an event which might reasonably be expected to occur following the trauma of operation.

There is, I think, general agreement nowadays that venous stasis and pressure on the calf veins during operation in association with circulatory thrombosis do cause minimal thrombosis in the small veins of the calf and that subsequent massive thrombosis is an extension of the process, and it behoves us therefore to seek carefully for this extension with all the means at our disposal. While I am sure that Mr. Greig's observations are correct, I think that they do not go far enough and afford no justification for his conclusions, and for the reasons given I would deprecate their acceptance at the present time when post-operative thrombosis is still a major factor in otherwise successful surgery.—I am, etc.,

London, E.1. R. D. POPHAM.

Toxoplasmosis

SIR,—The report by Mr. A. B. Nutt and others of the second case of toxoplasmosis in England (October 22, p. 905) prompts me to record the probable diagnosis of a third. I have not previously reported this case, since there was no confirmation by serum tests or histology. Most clinicians are now aware of the possibility of toxoplasmosis in considering the diagnosis of infantile encephalopathies. A tentative diagnosis has indeed

become rather fashionable, but the paucity of case reports suggests that the disease is rare. Serum tests, however, seem often to give inconclusive results, and prolonged search may be required to show the parasite in sections of fatal cases. It is probably as well, therefore, to put on record cases in which there is a high probability of a correct clinical diagnosis, even in the absence of biological confirmation.

The diagnosis in the case now reported rests upon the development in an infant of intermittent jaundice with steatorrhoea and acholic stools, enlargement of liver and spleen, progressive mental defect with blindness due to choroido-retinopathy, possibly deafness, and extreme hypotonia. No cerebral calcification was detected and there was no gross hydrocephalus. Dysplasia of the skull bones was a feature, but no pathological abnormality was detected in cartilage bone. The infant died of bronchopneumonia. There was rhesus incompatibility with the mother's blood, but no kernicterus or other evidence of erythroblastosis. Syphilis, pancreatic and parathyroid disease, and the storage diseases were excluded so far as possible. The parents were unrelated.

The child, the third in the family, was a girl born in March, 1947. She was first seen at the age of 3 months. Birth weight was 3.3 kg. Delivery was spontaneous after a slow labour with uterine inertia. It is not certain whether normal meconium was passed. At the eighth or ninth day jaundice developed, with pale stools: the jaundice disappeared after some days, but the stools remained very pale and only showed an approach to normal colour towards the end of her life. Jaundice reappeared at intervals and was present at the first examination in June, 1947, when she appeared as a small but vigorous infant, with widely open skull sutures and open, large conjointed fontanelles. The skull circumference was 15 in. (38 cm.). The liver was moderately enlarged. She was admitted to hospital for study, and was found to have a severe steatorrhoea with normal lipase activity; trypsin was demonstrated by duodenal aspiration, which also showed some bile pigment. Radiographs of the skull showed no distinctive lesion and were later scrutinized for cerebral calcification without result. No diagnosis was made. She left hospital and was seen in September, aged 6 months. There was now obvious regression in activity: she could not raise her head, would grasp, but not reach out. The liver seemed larger. Bright blood had been seen in the stools on several occasions. Head circumference was 16 in. (40.5 cm.). She was examined again in November and now failed to follow a light: the pupils gave normal reactions and there was no opacity in the media. A diffuse retinopathy was present, with much pigment gathered around atrophic patches. She gave no reaction to loud noises. The sutures and fontanelles were still widely open.

In February, 1948, she was reported nearly to have died during an attack of pneumonia. She was examined again in March, now aged [illegible] months, when the only new facts noted were a palpable spleen and the development of an extreme hypotonia. She died at home shortly afterwards. An autopsy revealed no light on the diagnosis. There was no gross hydrocephalus: the liver was large (555 g.) and pale, the thymus large, and the suprarenals very small. Sections showed no evidence of storage disease nor of fibrocystic pancreas.

The possibility of toxoplasmosis was not considered in this case until Jacobi and Segorin's report appeared (*Lancet*, 1948, 2, 926). Professor Beattie kindly examined the mother's serum in February, 1949, with negative result, and on his advice further specimens were sent to Dr. Sven Gard at Stockholm. A positive test was found to a titre of 1:10 with freeze-dried serum, but a second examination with untreated serum gave no result. Sections from many organs were retrospectively examined for parasites without any being identified.—I am, etc.,

Farnborough, Kent. DUNCAN LEYS.

Operative Treatment of Varicose Veins

SIR,—Mr. J. B. Oldham (September 10, p. 597) quotes me as carrying out the retrograde injection of varicose veins at the operation of ligature of the saphena magna. I wish to confirm this and also state my present evaluation of this practice.

I have just finished a three-year period, October, 1946, to September, 1949, during which most of the gross varicose veins under my care have been treated by the procedure of ligature at the groin or popliteal space and ankle, then internal mechanical abrasion of the saphena trunk, alternated by the fractional insertion of P25G solution (phenol crystals 2½%, glucose 25%, glycerin 25%, gelatin 0.25%); 1–2 ml. are inserted at a time, 7 ml. being injected at the groin through the long needle, starting at the knee and withdrawing, and 5 ml. are similarly inserted at the ankle from the knee downwards. I am much indebted to Mr. Riddoch, of Birmingham, for demonstrating to me the internal abrasion and telling me of his phenol (2%) and glycerin (30%) sclerosing fluid.

I have seen most patients since their operation at increasing intervals of one to six months, when visible and palpable varices have been injected as necessary with P25G solution. I am now examining them one to three years after this treatment. The results are excellent, and I am enthusiastic about the method. It is a compromise between effectively destroying the superficial varicose condition on the one hand and the danger of deep thrombophlebitis and a propagatory clot with embolism on the other.

During these three years my assistants and I have dealt with over a thousand patients. There have been no fatalities, and so far as I am aware only two instances of mild deep thrombophlebitis (both completely recovered) and one of pulmonary embolus. The latter is approximately the expectation of embolism after any surgical operation. I have made a point of inspecting all old patients. This method is effective and safe. Elsewhere I shall record an experimental variation which proved not to be safe nor so simple, and which demonstrated by contrast the effectiveness and innocuousness of the above technique.

With regard to chronic ulcers of the leg, may I say that no matter what the cause, and they are numerous, the treatment is almost the same. A bandage (not "elastoplast"; "lestreflex," or diachylon are less irritant and as effective) applied after the principles and practice laid down by Dr. Baynton in 1797 and by Mr. Dickson Wright from 1929 onwards by a trained and careful medical man will achieve what patients consistently describe as a "miracle of healing." Ointments, "sulpha" drugs, and penicillin creams, generally used and often ineffective, can be finally abandoned.—I am, etc.,

London, W.1. HAROLD DODD.

Modern Trends in Radiology

SIR,—It is now time for someone to write in support of Dr. James F. Brailsford and his views (October 1, p. 724), for he is not wholly wrong; indeed, he may well be largely right. As a specialist who tries to place his specialty in perspective and to prevent its abuse he deserves commendation and not castigation. His reward, however, is denunciation; and the tone of some letters in your issues of October 15 and October 22 suggests that their authors would feel much more at ease if Dr. Brailsford's views were suppressed. If so, then these views merit increased attention.

It seems futile to deny or ignore the truth of one main contention—namely, that radiography is being used extravagantly. For years a progressive increase in requests for *x*-ray examination has been apparent; truly the period of idolization is well under way. It would be reassuring to believe that such requests were based on sound clinical judgment and showed no taint of desire to drop the substance for the shadow. The evidence is to the contrary. Some doctors, moreover, nursing their *bête noire* of the insidious or atypical case and determined not to be caught out thereby, make requests for *x*-ray examination on the flimsiest pretexts, and while this determination is unquestionably laudable it would be more convincing if it showed a wider range and more discriminate selection of special examinations—e.g., the less convenient and less glamorous bacteriological examination of human excreta which may be even more important. Again, the unenlightened demands of patients themselves play some part; groundless fears can often be allayed in this way, so a radiograph is prescribed with or without medicinal adjuncts but certainly with more therapeutic effect.

The growing subservience to an instrument which has received medical acclaim, Government approval, and legal recognition is shown by the numbers and variety of cases now sent for *x*-ray examination in which radiography is unlikely to be of any value and therefore wasted. Many patients with clinically average and recognizable conditions,

such as bronchitis, mitral stenosis, congenital hydrocephalus, are sent for plain radiography "just in case." In case of what? Is there, then, no pattern of disease? The same attitude is manifest in cases with definite lung disease: the repeated routine radiography of firmly calcified lesions, of inert fibrosis, of established bronchiectasis; the anxious scanning of the shadow of a tuberculous lesion for activity in an effort to read what may not be written. Why this monotonous and melancholy admission of the mastery of matter over mind? Obviously the complete diagnosis is expected. Precise analogy is difficult, but there is some similarity in this to the diagnosis of a weighing-machine, which, by showing a person's weight on one side of a card, demonstrates thereby its competence to reveal his character on the other.

The proper function of radiography is to serve medicine and not to usurp its place. Nevertheless it is a powerful instrument, worthy of a high place. It is, however, unusually open to abuse, from which it must have protection. It will not be protected by passive silence, nor by adopting the oblique suggestion made to you, Sir, that Dr. Brailsford might be "muzzled" by denying him "space in a scientific journal." I hope you will be able to give him as much space as he needs. —I am, etc.,

Glasgow. J. S. GEMMILL.

Tuberculosis: Certain Unexplained Mortality Figures

SIR,—I should be very much obliged if you would permit me to reply briefly to Dr. Ian Sutherland's letter (October 15, p. 869) in order to correct certain misconceptions and inaccuracies. Dr. Sutherland's views on the mortality due to respiratory tuberculosis in Scotland and England and Wales are, as far as they refer to my letter (September 24, p. 706), utterly beside the point. I was not concerned, as he erroneously assumes, with deciding whether the mortality due to respiratory tuberculosis in Scotland in young adults was or was not worse than it is in England and Wales. Nor was Mr. Walter Elliot's address (August 6, p. 297) concerned with this question, for the simple reason that the north-south gradient of mortality due to tuberculosis is a long-established fact. Mr. Elliot's problem, and mine, was the deterioration of the *crude* death rate in Scotland since 1939, for which I have suggested the ageing of the population as a possible cause, operating, maybe, in conjunction with other causes.

I have not, as Dr. Sutherland inaccurately states, claimed to explain most of the changes in the death rate for tuberculosis since 1939. On the contrary, I have emphasized that the statistical explanation for the deterioration of the crude death rate did by no means exclude a concomitant rise in the age-specific death rate of young persons.

The third inaccuracy in Dr. Sutherland's letter is the statement that I had failed to make a full examination of the mortality at specific age groups, and this misstatement seems to recoil upon the critic himself. For not only has he overlooked the table in which mortality due to respiratory tuberculosis for the sexes and females in the relevant four age groups is given from 1939 to 1946, and from which certain conclusions were estimated, but he has failed himself to look at his own figures as according to which the mortality of males in Scotland per thousand living has changed (by age groups) as follows:

	15–24	25–34	35–44	45–54
1939–41 ..	80	105	105	115
1945–7 ..	82	104	100	113

The rate has thus dropped in three age groups and not risen significantly in the fourth. All this is contrary to his conclusions and confirms mine.

Apart from this, it is even misleading to declare that "these mortality rates are unaffected by changes in the age distribution of the population." Since each of the age groups comprises 10 years of age, these rates are really crude death rates for each of the four decades in question. Comparisons on the basis of such rates between different countries or different periods are therefore valid only under the assumption that the two age distributions within the 10-year age groups are identical. It goes without saying that such an assumption is not always justified, and the greater the difference between the overall age distributions of the two countries or in the two periods the less justifiable becomes the assumption. This must be kept in mind when considering the rise in the death rate for older people, males (55 and up), in Scotland.

The comparison with England and Wales in my own letter was not intended to show, as Dr. Sutherland seems to imply, that there was no difference in the mortality due to tuberculosis in the two countries, England and Wales and Scotland, but, on the contrary, to explain why the movement of the death rates in the two countries was different. As regards his conclusions about the female age group between 15–34, he has overlooked that I have already drawn attention to the fact that for this female age group we must assume a physical cause responsible for the deterioration in the death rate and that the statistical explanation was not to be adopted there.—I am, etc.,

Bristol. G. HERDAN.

Chloramphenicol in Typhoid Fever

SIR,—I was very interested in the article by Dr. J. C. Patel and his colleagues on chloramphenicol in typhoid fever (October 22, p. 908). It appears to me that there may be some significance—from a therapeutic point of view—in the fact that of six typhoid cases treated three died—all within 48 hours of treatment being commenced (at 48 hours, 26 hours, and 40 hours). It appears that the mode of death in the 48-hour case was circulatory failure; the authors write, "Whether this was due to the drug or the disease is difficult to say." As regards the 40-hour case, there was hyperpyrexia and circulatory failure, and the authors say that "it could well have been hyperpyrexial reaction during the course of the disease, or it may have been due to rapid lysis of a large number of organisms."

I take it that a hyperpyrexial reaction in the course of the disease is likely in itself to be due to an additional release of endotoxin from lysis of organisms, and if this is so the problem is whether the body unaided would have induced the lysis at that particular time anyhow or whether it is more likely to have been a genuine combined operation of body plus drug In the 26-hour case the authors say, "Probably chloramphenicol did not get a chance to act." Is it quite certain that this is so? According to the pamphlet issued with the drug, maximum blood levels can apparently be quickly achieved, at any rate in normal health, and, given adequate absorption, I think it unproved that 26 hours is too short a time in which to achieve appreciable action. I think it is therefore not impossible that chloramphenicol given in maximum dosage to a hypertoxic patient may be capable, by causing a sudden additional release of endotoxin, of precipitating a grave situation. Dr. F. Murgatroyd, in a description of a case of typhoid fever treated with chloramphenicol (May 14, p. 851), says, "In the first 24 hours the patient's general condition became markedly worse, and this gradually improved." It is true that two recent cases of paratyphoid fever successfully treated with chloramphenicol at this hospital did not demonstrate a clinically perceptible initial deterioration, but they were of favourable age groups (4½ years and 19 years) and though poorly were not hypertoxic.

If there is a danger of this effect it would be nothing new in medicine. It is true that in our use of sulphonamides and penicillin bold tactics in early dosage are advised and are both safe and rewarding. It does not follow, however, that in severe cases the first grand onslaught of the drug may not increase discomfort from toxaemia, though not to a dangerous degree. I have, however, no proof that this does occur in the treatment of coccal and bacillary infections with these drugs.

The matter is otherwise in antisyphilitic therapy, where in certain types of tertiary lesions it is well known that a dangerous Jarisch-Herxheimer reaction can be set in motion by unduly comprehensive early therapy. The danger here is not from toxaemia but from a too extensive clash of drug and organism. The parallel is perhaps closer in malaria, where "the sudden destruction of such a large number of parasites as is effected by intravenous quinine may liberate a dangerous or even fatal amount of toxin into the blood stream" (Lipscomb, F. E., in Conybeare's *Textbook of Medicine*, 1945, p. 179).

Finally, in the treatment of human brucellosis due to *Br. melitensis* in Mexico with "aureomycin," Spink and his

colleagues (*J. Amer. med. Ass.*, 1948, **138**, 145) speak of a sharp reactive rise of temperature on beginning treatment and mention the occurrence in some cases of an alarming temporary fall of blood pressure. They recommend a smaller initial dose of aureomycin (in the first two days) to overcome this effect. Possibly in the treatment of the more severe cases of typhoid fever with chloramphenicol a similar strategy might be the safer course.—I am, etc.,

Coventry. J. F. GALPINE.

The Acute Throat

SIR,—It is good to find more space in the *Journal* being devoted to subjects of particular interest to general practitioners, and I am sure most of us will have derived benefit from Dr. T. Anderson's article on "The Acute Throat" (October 15, p. 860). Nevertheless I feel that one statement made by Dr. Anderson should not go unchallenged. Of sulphonamides he writes, "The efficacy of these drugs has never been convincingly demonstrated in such conditions. Since they are undoubtedly toxic materials, carrying appreciable risks of sensitization, their administration is inadvisable, and in certain conditions may even be dangerous."

Probably everyone will agree with Dr. Anderson that the complaint of sore throat is one of the commonest made to the doctor, and further that outbreaks of acute tonsillitis are most frequently streptococcal in origin. I was taught, and my very limited experience has confirmed, that sulphonamides are of very great benefit in streptococcal infections. It is hard, therefore, to understand Dr. Anderson's first sentence in the paragraph quoted above. Surely the effect of sulphonamides in streptococcal infections is not doubted.

The alternative is penicillin. I agree that local therapy with lozenges is completely inadequate, and therefore intramuscular injections are necessary. Their efficacy is not doubted, but to suggest to a busy G.P. that he administer four-hourly injections of penicillin to all but the mild throat infections (for which aspirin, etc., are effective) is to suggest the impossible. He would not get through his day's work in 24 hours. Alternatively, to suggest that he give two or three injections of procaine penicillin for the first day and then carry on injections for seven days also demands very considerable time, and is in my opinion unnecessary in the great majority of cases if sulphonamides are used.

Further, while the difficulty of examining the writhing youngster is dealt with, no mention is made of the writhing youngster waiting for his second or third injection. The G.P. would be wise to heed the comfort of his patients, particularly children. Most of them will take crushed tablets, but in any case there are now available elegant raspberry-flavoured preparations of sulphonamides which are quite palatable. But not many submit to repeated injections of penicillin without a struggle, and some put up a resistance that professional fighters might envy.

I feel it would be better to reserve penicillin for those cases due to organisms which are penicillin-sensitive but which sulphonamides do not affect, and also to use it in conjunction with sulphonamides for the very severe streptococcal cases. To sum up, I should say that, while sulphonamides are undoubtedly toxic and certainly carry some risk of sensitization, and while in some conditions they may even prove dangerous if used injudiciously, nevertheless, and bearing these facts in mind, they are by far the most useful drugs at our disposal for dealing with these conditions in general practice.—I am, etc.,

Harrogate. D. C. WILLIAMS.

SIR,—In the article by Dr. Thomas Anderson on the acute throat (October 15, p. 860) the use of bismuth in the treatment of acute non-specific infections of the throat and upper respiratory tract is not mentioned. I feel this method of treatment merits wider recognition than it has received in this country.

The original paper on its use by Monteiro, of Rio de Janeiro (*Ann. Oto-laryng.*, 1934, **4**, 557), was followed by 46 papers in South America in seven years which corroborated his original work and verified his conclusion that bismuth therapy was specific in effecting recovery in the majority of these infections in 48 hours. The need for intramuscular injection appears to have been the main objection to its use in the treatment of these infections, but with the introduction by J. S. Stovin in 1944 of the rectally absorbed compound bismuth heptadiene-carboxylic acid this disadvantage disappears.

Following the reports of successful results in many papers, a trial was undertaken in 1947 in the Queen Elizabeth Hospital in Birmingham, but as the salt used by Stovin was not available my colleague, Professor K. D. Wilkinson, suggested the use of bismuth et sodii tartras (*B.P. Add. 1*), 1 gr. (65 mg.) of the salt in 15 gr. (1 g.) of cocoa butter used as a rectal suppository. This was described by us in articles published in the *Birmingham Medical Review* (1947, **15**, 170).

Our conclusions at that time were favourable, and experience during the past two years has supported this view. In my department in the Queen Elizabeth Hospital some 65 cases have now been treated by this method. They fall into two groups. The first were cases of continued pyrexia following tonsillectomy and other surgical procedures, and in these we found in four out of five cases the temperature became normal within 24 hours of the use of the bismuth suppository. The second, a smaller group, were members of the staff of the hospital suffering from acute tonsillitis, and although failures have occurred successful cases have been in the majority. The high proportion of successful results in this small series of cases suggests that bismuth therapy should be the primary treatment in acute tonsillitis, and encourages us to hope that with its use both the period of disability and the incidence of complications will be much reduced.—I am, etc.,

Birmingham. W. STIRK ADAMS.

SIR,—I have been disappointed with the first of your refresher courses in one respect—that of treatment. The author's treatment is the old-fashioned one of gargling, inhalations, and aspirin. Penicillin is discouraged and sulphonamides contra-indicated.

May I state that my experience is opposed to this? With sulphonamides patients feel much better in 24 hours, with no temperature and little pain or discomfort. Children especially respond well, and complications such as otitis are avoided. May I ask what controlled experiments have thrown doubt on the efficacy of sulphonamides?—I am, etc.,

Birkenhead. A. V. RUSSELL.

Teaching of Physiology

SIR,—The question raised in Professor D. H. Smyth's letter (October 8, p. 813) regarding restrictions on the use of animals—in particular, dogs and cats—in the teaching of physiology in this country is, I feel, an interesting one, for no one seems to have stated clearly what these undesirable restrictions are. I can assume that no leading physiologist in this country would advocate entirely unrestricted vivisection for all and sundry. Let us then examine the restrictions as they exist to-day in the terms of the Cruelty to Animals Act (1876). I find that they are six in number, and in all but two the provisions can be avoided by obtaining the necessary certificates to prove that such restrictions would frustrate the experiment or the advancement of science.

The two exceptions are those which (1) forbid experiments for the attainment of surgical skill, and (2) forbid exhibitions in public. I suppose there is no responsible person who would wish to remove the second of these. The first does not concern the physiologist, and therefore need not concern us at the moment, but, in passing, I would say that I have never heard it stated that British surgeons are any whit inferior to surgeons of other countries on this account.

Now the certificates which are granted by the Home Office (supplementary to the licences) must be signed in the first place by one or more responsible persons, including the presidents of the Royal Colleges, medical or veterinary. They permit the following procedures: (1) experiments on animals in illustration of lectures before students; (2) experiments not directly for the advancement of physiological knowledge, and repetitive experiments to test former discoveries; (3) experiments dispensing with anaesthetics if they would interfere with the success

or object of the experiment; (4) recovery of the animal from the anaesthetic and observation for prolonged periods if killing the animal would frustrate the object of the experiment; (5) the use of cats, dogs, horses, asses, or mules if the particular animal can be shown to be necessary to the success of the experiment. In each case, it should be clearly understood, the certificate must state that the particular dispensation required is necessary; thereafter the granting of the certificate by the Home Office follows as a matter of course—at any rate I have never heard of an instance in all the 73 years of the Act in which it has been refused. Is it suggested that the eminent signatories refuse to countenance scientific investigation of value, or that types of experiment not deemed necessary to such investigation should still be performed at the whim of the research worker? May we be informed to which restrictions under the Act objection is taken?

There is, indeed, a "pain clause" which should be mentioned. It is attached to all certificates and is sometimes claimed to be a "restriction." It says that any animal in *severe* or *prolonged* pain must be painlessly killed even if the main result of the experiment has not been achieved; but even after this point the animal may still be in moderate pain which the experimenter thinks will not endure without his being required to kill it. Since, however, there is no standard, nor can be any, of what constitutes severe pain or prolonged pain, it is difficult to see that the experimenter need be hindered in his work. At any rate I should be glad to hear of any instance in which it has been put into effect. Is it felt that this "condition" restricts the teaching of physiology?

An answer to these questions would, it seems to me, clarify the issue.—I am, etc.,

Camberley, Surrey M. BEDDOW BAYLY.

A Long Gestation

SIR,—As there has been a great deal of discussion recently of the length of the human gestation period, I thought you and your readers might be interested in the appended extract from the Saga of the Volsungs, describing a six-year gestation period terminated by caesarean section. The Saga of the Volsungs in written form dates from about the twelfth century, but was probably handed down for many centuries orally.

"So, as the tale tells, the queen soon knew that she was big with child, but a long time wore or ever she might give birth to the child: so it befell that the king must needs go to the wars, after the custom of kings, that he may keep his own land in peace: and in this journey it came to pass that Rerir fell sick and got his death, being minded to go home to Odin, a thing much desired of many folk in those days. Now no otherwise it goes with the queen's sickness than heretofore, nor may she be lighter of her child, and six winters wore away with the sickness still heavy on her; so that at the last she feels that she may not live long; wherefore now she bade cut the child from out of her; and it was done even as she bade; a man-child was it, and great of growth from his birth, as might well be; and they say that the youngling kissed his mother or ever she died; but to him is a name given, and he is called Volsung." (William Morris's translation.)

I know little or nothing of anthropology, but it has always seemed to me that the story of the six-year gestation period may have arisen from a custom, mentioned in the Old Testament, of heirs being produced for a man who died without issue by impregnation of the widow by the dead man's brother or other near relative; and that in the case of Volsung the widow of Rerir did not become pregnant for six years after his death.—I am, etc.,

Cremorne, New South Wales. MADELINE N. GORS.

Congenital Pyloric Stenosis

SIR,—The following report of three cases of congenital hypertrophic pyloric stenosis in one family may be of interest in view of Dr. J. L. Adlington's report (October 1, p. 740). The incidence in three brothers is rare. The children here described were the first, second, and third children; the fourth—a girl—was completely unaffected.

Case 1.—The first child, weighing 7 lb. 5 oz. (3.32 kg.) at birth, was admitted to the Royal Aberdeen Hospital for Sick Children on February 24, 1939, at the age of 5 weeks, with a history of vomiting after most feeds since 3 weeks old. The feeding had been changed from breast milk to lactic-acid milk, then to Nestlé's, and then to cow's milk, with some improvement in the condition for a few days after each change. The child was always hungry for feeds and had been constipated for eight days prior to admission. Peristalsis was noted, and soon after feeds projectile vomiting occurred. A pyloric tumour was palpable in the epigastrium to the right of the mid-line. Rammstedt's operation confirmed the diagnosis, but the child died six days after operation. Post-mortem examination revealed a generalized peritonitis.

Case 2.—The second child was born on January 12, 1940, and admitted to hospital on February 2, 1940, at the age of 3 weeks. The history was that three days before admission the boy, who was well apart from mild icterus which dated from birth, started vomiting about half an hour after feeds. The vomit was not projectile but was copious. Constipation had been troublesome for a week. In hospital he was found to be moderately dehydrated and the abdomen was distended. Some jaundice was present. Visible peristalsis occurred and vomiting of a forcible character persisted after every feed. After correction of dehydration Rammstedt's operation was performed on February 5, and a typical pyloric tumour was incised. The condition after operation was good. Gastric lavage on one occasion showed a small amount of fresh blood, but all feeds were taken well and retained. Progress was satisfactory, and he was *discharged 10 days after operation. Follow-up, four, eight, and* 16 weeks later, showed that he was a keen, bright child, and was well nourished. Development was normal.

Case 3.—The third male child of the family was born on January 3, 1943, and was breast-fed for three weeks. Feeding was then changed to dried milk because of repeated small vomits after feeds. The baby was constipated. By the age of 8 weeks the feeding had been changed three times without any improvement in the vomiting or constipation, and it is remarkable that the condition was not suspected by the parents. When the infant was brought to hospital the vomiting was projectile, peristalsis was visible, and a pyloric tumour palpable. Two days after admission the boy was operated on and the thickened pyloric muscle incised down to the mucosa. After operation there was slight sickness, which was controlled for three days with "eumydrin." The child was discharged 13 days after operation, taking full feeds and gaining weight steadily.

In the later history of the two surviving brothers it is perhaps worthy of note that both boys had infantile eczema during the first year and both required removal of tonsils and adenoids at the same time in December, 1945. Subsequently, in May, 1947, both boys were in hospital at the same time for appendicectomy—in each case a history of acute severe abdominal pain with vomiting being given. The appendix of both children was inflamed and infected, that of the younger showing pus and incipient abscess formation. Inquiry into the family history has not revealed any other known relative in whom pyloric stenosis has occurred. The parents are not consanguineous. Both boys are at present in excellent health. The cases were admitted to the Royal Aberdeen Hospital for Sick Children under the care of Professor John Craig, who has kindly given permission for the publication of this report. My thanks are due to him for his help and advice.

—I am, etc.,

Aberdeen. JOAN M. BURRELL.

Dysentery in Monkeys

SIR,—With reference to the letter by Dr. R. E. Rewell and Colonel R. F. Bridges (October 15, p. 876), at the Central Research Institute, Kasauli, India, in 1940, in the search for a suitable antigen to be used in the event of epidemic dysentery in war, monkeys were used by me as experimental animals. These were immunized with a Flexner strain of antigen isolated from a suffering monkey and closely related in antigenic content —shown by feciprocal absorption tests—though not exactly similar, to one of the commoner Flexner human types. It was found that these animals could be immunized by doses of a detoxicated vaccine, details of the preparation of which can be seen in a paper published in 1942 (*Ind. J. med. Res.*, 1942, 30, 213). The result of this research in the monkey as the experimental animal, using its own infective bacterium as antigen, added much to my belief in the efficiency of parallel methods of preventive T.A.B. immunization in man.—I am, etc.,

Glasgow. W. LEONARD FORSYTH.

colleagues (*J. Amer. med. Ass.*, 1948, **138**, 145) speak of a sharp reactive rise of temperature on beginning treatment and mention the occurrence in some cases of an alarming temporary fall of blood pressure. They recommend a smaller initial dose of aureomycin (in the first two days) to overcome this effect. Possibly in the treatment of the more severe cases of typhoid fever with chloramphenicol a similar strategy might be the safer course.—I am, etc.,

Coventry. J. F. GALPINE.

The Acute Throat

SIR,—It is good to find more space in the *Journal* being devoted to subjects of particular interest to general practitioners, and I am sure most of us will have derived benefit from Dr. T. Anderson's article on "The Acute Throat" (October 15, p. 860). Nevertheless I feel that one statement made by Dr. Anderson should not go unchallenged. Of sulphonamides he writes, "The efficacy of these drugs has never been convincingly demonstrated in such conditions. Since they are undoubtedly toxic materials, carrying appreciable risks of sensitization, their administration is inadvisable, and in certain conditions may even be dangerous."

Probably everyone will agree with Dr. Anderson that the complaint of sore throat is one of the commonest made to the doctor, and further that outbreaks of acute tonsillitis are most frequently streptococcal in origin. I was taught, and my very limited experience has confirmed, that sulphonamides are of very great benefit in streptococcal infections. It is hard, therefore, to understand Dr. Anderson's first sentence in the paragraph quoted above. Surely the effect of sulphonamides in streptococcal infections is not doubted.

The alternative is penicillin. I agree that local therapy with lozenges is completely inadequate, and therefore intramuscular injections are necessary. Their efficacy is not doubted, but to suggest to a busy G.P. that he administer four-hourly injections of penicillin to all but the mild throat infections (for which aspirin, etc., are effective) is to suggest the impossible. He would not get through his day's work in 24 hours. Alternatively, to suggest that he give two or three injections of procaine penicillin for the first day and then carry on injections for seven days also demands very considerable time, and is in my opinion unnecessary in the great majority of cases if sulphonamides are used.

Further, while the difficulty of examining the writhing youngster is dealt with, no mention is made of the writhing oungster waiting for his second or third injection. The G.P. wise to heed the comfort of his patients, particularly children. Most of them will take crushed tablets, but in any case there are now available elegant raspberry-flavoured preparations of sulphonamides which are quite palatable. But not many submit to repeated injections of penicillin without a struggle, and some put up a resistance that professional fighters might envy.

I feel it would be better to reserve penicillin for those cases due to organisms which are penicillin-sensitive but which sulphonamides do not affect, and also to use it in conjunction with sulphonamides for the very severe streptococcal cases. To sum up, I should say that, while sulphonamides are undoubtedly toxic and certainly carry some risk of sensitization, and while in some conditions they may even prove dangerous if used injudiciously, nevertheless, and bearing these facts in mind, they are by far the most useful drugs at our disposal for dealing with these conditions in general practice.—I am, etc.,

Harrogate. D. C. WILLIAMS.

SIR,—In the article by Dr. Thomas Anderson on the acute throat (October 15, p. 860) the use of bismuth in the treatment of acute non-specific infections of the throat and upper respiratory tract is not mentioned. I feel this method of treatment merits wider recognition than it has received in this country.

The original paper on its use by Monteiro, of Rio de Janeiro (*Ann. Glasgow. W. LEONARD FORSYTH.

Antiseptics for Minor Dressings

SIR,—May I comment on Dr. I. B. Sneddon's letter (October 1, p. 759), which rightly criticizes the local use of sulphonamides? Dr. Sneddon states that "penicillin powder is 99% sulphathiazole." This statement is liable to misinterpretation; the preparation which he presumably has in mind is a mixture of penicillin and sulphathiazole used for local application. The use of this mixture does incur, as Dr. Sneddon points out, the risk of a sulphonamide dermatitis.

In this hospital, however, we have found that a useful alternative is a mixture of penicillin and lactose. The lactose is sterilized by heating in a hot-air oven for eight hours at a temperature of 140° C., and when cool is mixed with calcium penicillin to give a final strength of 5,000 units per gramme of finished product. We have used this preparation for several years and have found it a convenient method for applying penicillin locally.—I am, etc.,

Hertford County Hospital. JOHN C. H. HANSON, Chief Pharmacist.

Conceptions of Right and Wrong

SIR,—Dr. Frederick Dillon (August 27, p. 485) asked for an authoritative meaning of the word "wrong" as it is used in the M'Naghten rules, and is resentful when Dr. J. E. Wilson, in replying (September 24, p. 711), seeks to give him his answer together with an authority for it, although he does so, somewhat unhappily in my view, by quoting at length the answers of the judges. If Dr. Dillon merely wished for an answer in terms of yes and no, as he states in his more recent letter (October 8, p. 818), he could have had it by reference to any good standard work—for example, those of Glaister or of Kenny. The latter, indeed, in his *Outlines of Criminal Law* has added the word "morally" in summarizing the judges' answers.

That morally wrong and not legally wrong is the meaning was finally established by the Court of Criminal Appeal in 1916, when the question was considered by that court in the case of Rex *v.* Codere, but morally wrong not by the standard of the accused, as Dr. Dillon would apparently construe it, but by "the ordinary standard adopted by reasonable men" with reference to the particular act. Further, if the prisoner knew in actual fact that the act was contrary to law it must be presumed, at least in the case of serious crimes, that he knew it to be wrong by that ordinary moral standard.

It will follow from this, therefore, that if prosecuting counsel can prove, as the Attorney-General sought to do in the Haigh case, that the prisoner knew the act to be wrong legally, then he must be taken to have known it to be wrong morally, as required by the rule. Even before Rex *v.* Codere a prisoner such as Haigh who knew his act to be legally wrong would have been held responsible on the authority of the first of the answers of the judges, already quoted by Dr. Wilson.

Much righteous indignation and sympathy for the criminal appears to be wasted by medical men on account of the supposed inadequacy of the M'Naghten rules. The function of the law is to protect the community, and, while with a better understanding of insanity there has been a gradual widening in the application of these rules, it must rest with medicine to throw more light on mental disease and so make possible a revision of the law, unless, indeed, the probable abolition of capital punishment reduces their importance.—I am, etc.,

Aberdeen. DOUGLAS MCBAIN.

Distinction Awards for Consultants

SIR,—The history of the dispute on this subject is discussed at some length in your leading article (October 1, p. 745). The writer gives the impression that there was no criticism of the report of the Spens Committee on remuneration of specialists at the time of its publication (June, 1948). That this was not in fact the case is shown by consideration of my letter in the *Journal* of July 3, 1948 (p. 48), quoted in your leading article in the same issue (p. 31). Although my letter expressed warning and criticism of the proposed method of making distinction awards and was, I believe, the first one published in your journal at that time, I made it quite clear that my views, though personal, did in fact represent the views of other specialists, if not indeed the majority of consultants.

It is necessary to remind ourselves that most specialists are far too busily engaged in medical work to find time to express their opinions through your columns on the multitudinous weaknesses of the health services; more especially is this the case when these opinions are in agreement with previous correspondence. Such was the position in July, 1948, and it is unfair to suggest that voices were silent until that of Dr. F. M. R Walshe was heard on August 13 (p. 383). I am the first to acknowledge precedence to the letter of Dr. Walshe in weight and authority, but I do claim that my letter had precedence in time to the extent of over one year and anticipated with a warning the troubles to come.

I range myself whole-heartedly behind Dr. Walshe in his utterances on this subject, and view with horror the threatening statement of Dr. H. E. A. Boldero (September 10, p. 594) that "money for these awards will not be available for any other purpose." If Dr. Boldero seriously believes that the specialists of this country want to grab as much money from the taxpayers as they can for distinction awards at the expense of the harmonious unity of the profession I cannot imagine what he takes us for unless he likens us to a hungry flock of vultures each struggling for the greatest part of the prey. Far more would we prefer to see the money handed back to the taxpayers on whose shoulders the exorbitant expense of the Health Scheme depends.

The one sensible suggestion for the distribution of the fund is made in your article—that it should be made available for posts in the higher grades of the Service. Although these would probably be whole-time posts, as a part-time consultant I would far prefer that the fund should be distributed evenly for all full-time consultants in compensation for their less pleasant terms of employment and their inability to pursue private practice, which the Minister has unsuccessfully strived to destroy. In this way we should at least avoid the demoralization of the present set-up, in which specialists are empowered to assess the merits of their colleagues in secret communications. Rather than by using public funds to disrupt the harmonious co-operation of specialists which has been a feature and a legacy of the past, surely we should strive to preserve the spiritual and moral qualities of our calling—qualities which are of far greater worth than extra financial remuneration.—I am, etc.,

Windsor. PHILIP H. WILLCOX.

Acknowledgments to Authors

SIR,—It is good that Sir Stewart Duke-Elder in his review of *Modern Practice in Ophthalmology, 1949* (October 22, p. 913) should remark upon the undesirability of using illustrations without acknowledgment to the authors of them—"an omission which, it is hoped, will not become a practice in British medical literature."

An author who uses an illustration without acknowledging its source cannot well escape the implication that it is his own. In a book just published are two illustrations: one is taken from a presidential address of the Ophthalmological Society, the other, a particularly good coloured plate, is taken from another book. Not only are these used without acknowledgment of any kind, but in the case of the latter the author has taken upon himself to alter the caption.—I am, etc.,

Salisbury. R. FOSTER MOORE.

Encouraging the Blood Donor

SIR,—The excellent work of blood depots and hospital transfusion departments has ensured against grave shortage of supplies of blood, but few hospitals can claim to have optimum stocks of blood all the year round. There are occasions, especially in holiday time, when stocks are low, even lamentably so, and on such occasions the admittance of a severe case of bleeding peptic ulcer or a severe pregnancy haemorrhage may be frightening. The necessity for giving Rh-compatible blood has increased the seriousness of low blood reserves, and the

advent of our new medical service is, of itself, unlikely to stimulate voluntary donation, rather the reverse. It behoves us, therefore, to consider the factors influencing the supply of blood to a hospital. These fall into two overlapping groups—factors affecting the enlistment of donors and factors concerned with the maintenance of established donor panels.

There is a strong tendency for the average individual to avoid thinking of personal responsibility in blood donation. Much more could be done to increase supplies by well-planned information in the Press, the cinema, the church, and even the radio to increase the feeling of personal responsibility. Comparatively few realize the sometimes enormous expenditure of blood in a modern hospital. The public would, I am confident, be more inclined to offer their services if they were impressed by more facts and given facilities for seeing for themselves what is done and what is required. Our present panels of unselfish citizens are proof that no monetary inducement is essential, though by way of compensation the French system of allowing additional food rations might be adopted.

Many would-be donors are deterred by a strong fear of blood-letting. Fear can be largely dispelled by allowing people to see for themselves how blood is withdrawn painlessly and by emphasizing the vital role of the blood donor in the recovery of so many hospital patients. Satisfied donors are themselves excellent agents for dispelling fears amongst their friends and acquaintances. A few energetic, public-spirited doctors have addressed groups of young adults (e.g., in youth clubs), thereby winning their interest and services in transfusion work. Such efforts could well be emulated by doctors, young and old, who are sufficiently interested in the welfare of their hospital.

In certain parts of the world, notably the U.S.A., blood expended on a patient has to be replaced in kind by a member of the family, where circumstances permit. Blood donors are paid for their blood in cash. The enlistment of healthy relatives, especially young adult relatives, as blood donors might be considered as a possibility in this country. Tactful inquiry and gentle persuasion on the part of the doctor could enlist the services of many helpers from this family source.

The blood donor is such a precious unit that particular care should be exercised in all our dealings with him or her. This implies, amongst other considerations, a courteous welcome, painless blood-letting, and appropriate refreshment in pleasant surroundings. The dissatisfied donor is unlikely to return. He may be dissatisfied with the abrupt wording of the letter from the hospital reminding him of his appointment, which perhaps reminds him more of income-tax returns than a mission of mercy. Or he may be displeased with the cold reception at the hospital or the clumsy and painful technique of doctor or nurse. He is unlikely to overlook lack of gratitude for his services. All donors deserve appreciation, especially those who have given many pints of blood or who have answered emergency calls. A personal letter from a senior hospital doctor would be a fitting expression of gratitude in these instances.

A donor panel can be adequately maintained only by constant vigilance and attention to detail. Many donors quietly drop their services either because they leave the neighbourhood or because they no longer wish to donate blood. In either case it frequently happens that the hospital is not informed of the termination of their services in good time. A blood donor panel, like clothing, requires constant repair and replacement.—I am, etc.,

London, S.W.17. A. WYNN WILLIAMS.

Co-ordination of Tuberculosis Schemes

SIR,—The figures quoted by Sir Andrew Davidson in a recent address, reported in the *Journal* of October 8 (p. 806), give convincing proof of the seriousness of the tuberculosis problem in Scotland. Sir Andrew states that the reasons for the continuing high incidence and mortality have not been elucidated. Doubtless there were, and are, many factors outwith control, but have there not also been administrative mistakes that could have been avoided?

For example, even when it became apparent that the servicing of sanatorium beds would be difficult for some time to come no country-wide move was made to make good the deficiency, in part at least, and temporarily, by the fullest possible use of the fever hospitals, where beds and staff were available. Had this been done our waiting-lists would not be so large to-day. Instead, cases in all stages of the disease, many of them highly infective, have been allowed to drift into the medical wards of general hospitals, where other patients, staff, and visitors provide contacts that may number hundreds every week and where adequate preventive measures are impossible. This surely violates every principle governing the treatment of infectious disease. If such cases are to be accommodated in general hospitals it must be in special wards, where conditions can be made to approximate sanatorium ideals.

Later in his address Sir Andrew Davidson advised that "the best possible use should be made of all hospital accommodation irrespective of the functions for which it was originally provided." I trust that in so saying he had in mind the use of special accommodation in general hospitals, and the valuable contribution that the infectious diseases hospitals could make to the solution of this problem.

Further, should not priority be given to all measures aimed at erasing this black spot from Scotland's health record? Any outbreak, however small, of enteric fever or infantile paralysis calls for and obtains immediate mobilization of all the forces at the command of the health authorities, and rightly so, but a similar sense of urgency has been lacking in the official attitude to the tuberculosis problem. Nor is it discernible to the degree that one could wish in the new hospital service, though efforts are being made to find more beds.

One might have expected in the recent grading of specialists some recognition of the magnitude and importance of the task facing workers in this field. But it would appear that the establishment of consultants in tuberculosis is likely to compare very unfavourably with that of other specialties. How, then, is the best type of recruit to be attracted to this vitally important service?—I am, etc.,

Dundee. G. RANKINE.

Fat Absorption

SIR,—A friend has suggested to me that a sentence I used in my Sharpey-Schafer Memorial Lecture (*Journal*, October 1, p. 719), when not considered in relation to its context, might give the impression that there may be no danger in the unrestricted use of mineral oils, either medicinally or as fat substitutes in food.

I must therefore correct that impression if it exists. Referring to the experiments of Frazer and his colleagues on the absorption of extremely fine emulsions of paraffin, I said: "Some alarm has been expressed on this account at the use of medicinal paraffin as a medicament and in cooking." In saying this I was solely concerned with the question of evidence that *dangerous amounts* of paraffin are actually *absorbed* from the intestine when it is taken by mouth in the ordinary way. This does not mean that there are not other dangers. Students of nutrition know them well, and they were referred to in a leading article in the *Journal* (June 12, 1948, p. 1141). With these, however, the lecture was not concerned.—I am, etc.,

Manchester. H. S. RAPER.

POINTS FROM LETTERS

Transmission of Syphilis

Dr. JESSIE M. CRAWFORD (Dartford) writes: Dr. Philip Simon's letter (October 8, p. 815) shows how very important is the taking of a blood test in every pregnant woman regardless of social standing or anything else. It is not necessary to take a case history from the syphilitic point of view till after a positive finding. Even then tact can elicit the necessary facts, and if the husband can be got to take treatment *pari passu* with the wife no apportioning of blame or breaking up of family relationships need ensue. So many people seem to sheer away from the question of syphilis because of the moral issues involved, particularly when an unexpected positive is found. It seems to me, especially now in the aftermath of war, that no one can afford to shirk his or her responsibility to the future generation in this respect. The modern child has a hard enough way to hoe without having the disadvantages of inherited disease thrown in.

Obituary

SIR RICHARD NEEDHAM, C.I.E., D.S.O., M.D. F.R.C.P.Ed., F.R.C.S.

Sir Richard Needham, who died at his home in London on October 24 at the age of 71, was for six years Deputy Director-General of the Indian Medical Service. He had done valuable work as an inspector of medical studies in India, and visited many medical schools in both Asia and Africa on behalf of the General Medical Council and also of the Colonial Office. He had been a member of the Council of the British Medical Association for six years. One of the most distinguished members of the Indian Medical Service, Needham was a man who combined eminence in his profession—in hygiene, administration, and education—with a most lovable personality.

Richard Arthur Needham was born in 1877 and educated at Owens College, Manchester, where he graduated M.B., B.Ch. in 1899 at the early age of 22. He was a house-physician at the Manchester Royal Infirmary and later a demonstrator in anatomy at the University. He joined the I.M.S. in 1903. The Service was then at its zenith; competition was keen and the successful entrants were of notably high quality. Nevertheless Needham early attracted attention by his keenness, initiative, and capacity for hard work. He saw service in North China from 1905 to 1908, and his observations and experiences there turned his interests towards preventive medicine. As soon as he could—in 1910—he obtained his D.P.H. Returning to India, he was selected to accompany a special mission to Tibet in connexion with the repatriation of Chinese troops from that country. Here his duties were largely preventive in character and were performed with great ability.

On the outbreak of the first world war Needham was appointed D.A.D.M.S. (Hygiene) at the base at Marseilles, and was responsible for the medical organization of the many transit camps which were established there and for the care and well-being of thousands of British and Indian troops who passed through that port. It was his conspicuous success in this difficult task which first brought to general notice his outstanding organizing ability, earned him his D.S.O., and dictated his next appointment as Officer on Special Duty in connexion with medical supplies to Mesopotamia after the breakdown of 1916. Equally successful in this assignment, for which he was awarded the C.I.E., his selection as Deputy Director-General in 1918 followed almost as a matter of course. This exacting appointment gave full play to Needham's great capabilities. It brought him into contact with almost every officer in the Service. He was faced with medical and health problems, involving those of medical education, over the whole of the revision subcontinent, which he toured extensively. Widely consulted on all matters of medical administration, his capital decisions commanded universal respect.

Towards the end of his tenure as D.D.G., Needham was appointed inspector of medical studies in India on behalf of the General Medical Council, an activity that continued for the remainder of his service. Medical education in the new Dominions owes much to this day to the high standards on which he insisted and persistently refused to compromise. On his return from Deputy Director-General he was invited to work out the constitution of a new Indian State Railways. The organization and criticism of the proposals in operation with the efficiency which stamped all his work. He proceeded to the degree of M.D. in 1920 and was elected F.R.C.P.Ed. in 1924. In 1923 and again in 1927 Needham represented India at the international sanitary conferences held in Paris. He retired from the I.M.S. in 1930 and was knighted in 1932. After his retirement Needham continued his work for the G.M.C. as its visitor to medical colleges abroad. He went to India again, and he reported on the state of medical education there and in Rangoon, Ceylon, Singapore, and Hong Kong. In 1939–40 he also visited for the Colonial Office the medical schools of Nigeria and Uganda. In the recent war, though over 60, he accepted the invitation of the Indian Red Cross Society to serve as their Commissioner in Egypt, a position he held until the disbanding of the Commission at the end of the war. Here he gave of himself as unsparingly as ever but at a cost he did not realize at the time; permanently impaired health was the price he paid for his strenuous exertions in Egypt.

Needham's clear, lucid mind, his quick grasp of essentials, and his power of succinct expression made him a remarkably fast worker; the amount of work he crammed into a day was prodigious. Yet he never appeared hurried, and always found time to listen to, and generally to help with, the problems of others. Genial and generous to a fault, he was intolerant only of slackness or subterfuge; these he hated and exposed ruthlessly. On the other hand there was no limit to the trouble he would take to help and promote the interests of men of his Service who he thought were "doing their stuff." Many of his juniors, among them the writer, will cherish the memory of his spontaneous kindness, his sound advice and warm championship, and his generous and delightful hospitality. India and the I.M.S. owed much to Dick Needham. Now India has lost a devoted and disinterested servant, the Service one of its most distinguished sons, and we a comrade and friend whose like we shall not see again. The sympathy of all who knew him will go out to Lady Needham. —J.B.H.

A colleague writes: The most notable years of Needham's service in India were those in which he was Deputy Director-General of the I.M.S. During this period he was one of the most prominent and popular figures in the official and social circles of Simla and Delhi. Both of the distinguished chiefs under whom he served relied on him to such an extent that he was generally looked on as the power behind the throne. It is no secret that, when the post of Director-General was about to become vacant through the retirement of Sir Charles MacWatt, Needham was regarded by his administrative colleagues in the Government of India as the most suitable officer to fill the vacancy. Indeed, he was exceptionally well qualified for the appointment in every respect, save only that he lacked the degree of seniority considered essential for the post. In the circumstances it was necessary to find another appointment for him, but owing to the long period during which he had been engaged in purely administrative work he came to the conclusion that he could not fill with satisfaction to himself the appointment to which he was gazetted or any other likely to be available for several years. Accordingly he felt compelled to take long leave preparatory to retirement, and his career in the Service was thus ended prematurely for no other reason than that he had achieved outstanding success at too early a stage.

In spite of his natural disappointment Needham did not yield to a feeling of frustration; he soon found an opportunity for undertaking a very important task for which he had unique qualifications. This was to serve on the Council of the British Medical Association and act as

THE INTRAVAGINAL TAMPON IN MENSTRUAL HYGIENE

An important clinical study

No. 3

Original Gynaecological and Obstetrical Research. Annual Report.

Tampax were given to 36 normal menstruating women, and they were instructed to insert one Tampax night and morning during and between their menstruation; that is, twice every day for one year. Vaginal mucosal biopsies, pH, bacterial flora, and glycogen contents of the vaginal mucosa were taken before, during, and after Tampax were used. To our surprise, the vaginal mucosa became much hypertrophied; the pH became more acid, which is helpful; the glycogen was increased and the bacterial flora was also improved. Tampax are made of cotton, and that is the reason they cause no harm, but produce a more healthy vagina.

Ten cases of senile vaginitis were instructed to insert one Tampax night and morning, and the vaginal mucosa in these cases became markedly hypertrophied. The alkaline vagina became acid and the reaction in the vagina became like that where estrogenic hormones had been used.

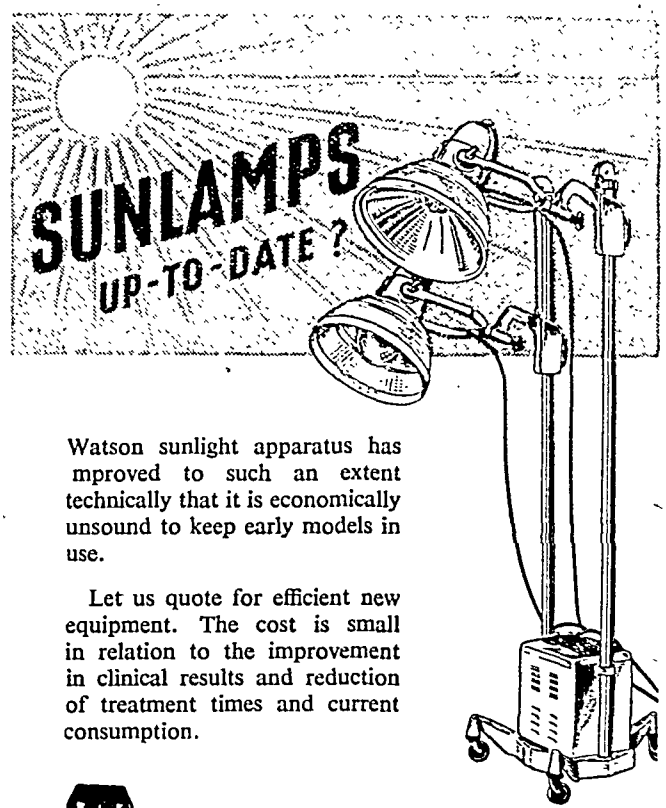
The normal non-pregnant vaginal mucosa also became so hypertrophied in some cases that it appeared like that of a pregnant woman. The vagina also became dried and appeared healthier than it was normally.

COTTON PACKS AND NORMAL MENSTRUATION

Tampax were used as successfully as perineal pads in 95 per cent of our 45 research cases. They were changed about as often as the pads. The psychological aspect of menstruation is in many cases relieved when the belt is no longer used. There was no blocking of the menstrual flow in the cervix in any of these cases.

Reprinted from the Medical Record and Annals, Houston, Texas, U.S.A., May, 1941

LEUCORRHOEA VAGINAL



Keeps the vagina dry. A dry method. In long standing cases of leucorrhoea where the patients have to wear a perineal pad almost all the time to keep the underclothes from becoming soiled, a Tampax will absorb the secretion and keep the vagina very dry. You will have won her confidence and then proper treatment can be instituted.

honorary adviser to the B.M.A. in its conduct of a campaign for the defence of I.M.S. officers against a concerted attempt to deprive them of the rights and prospects which had been held out as inducements to persuade suitable candidates to enter the Service. His unrivalled knowledge of Service matters was of the greatest help to the Association in the long struggle that followed, and the I.M.S. was indeed fortunate in having so able an advocate, especially as its members, serving mostly in isolated posts all over India and Burma, had no organization for the defence of their interests. Needham had the satisfaction of knowing that his voluntary efforts earned for him the high esteem of his fellow officers, but only those associated with him in the negotiations were able to realize the full extent of the debt of gratitude owed to him by every member of the I.M.S.

Wing-Commander H. M. Stanley Turner writes: It was a shock, not only to me but to my family, when we heard of the death of Dick Needham. We saw a lot of him in the days when he was on the Council of the B.M.A. and the Naval and Military Committee—in the days when we were trying to improve conditions of service for the Medical Services of the fighting forces. I have a lively recollection of innumerable informal committee meetings in my bedroom at all hours of the day and night during the annual meeting at Bournemouth, when wheels were busily working within wheels. Goodbody was chairman of the Naval and Military Committee at the time. Needham had a great sense of humour, but he never lost sight of the matter under consideration, although one could see by the twinkle in his eye that he never missed the funny side. He had a very clear and logical mind, which with his great Service experience and tact made him a tower of strength in our deliberations. He quickly grasped points under consideration which might easily become "sticky" with non-Service members of the committee. Both he and I were but recently out of the Service and had not had time to lose our knowledge of the probable reaction of the official mind to matters put forward by the B.M.A. I think this was of assistance both on the Council and in committee. His wide travels and outstanding work in connexion with medical education in our overseas possessions are too well known to require any word from me; but I have always regretted just missing him in Ceylon when he was there in that connexion. I always remember during the Bournemouth meeting in 1934, after a long period with our noses to the grindstone, he and I decided to give a miss to one of the many social functions and have a night out with my wife and young daughter in a sort of fun fair. He was just like a schoolboy let loose, and we had a most hilarious time sampling all the sideshows. We still speak of it. Needham will be badly missed.

J. E. BARNARD, F.R.S.

Mr. Joseph Edwin Barnard, who was well known for his work on ultra-violet microscopy, died at his home at Addiscombe, Surrey, on October 25 at the age of 80.

At a very early age, although still engaged in his father's business, he began to spend most of his spare time at the Lister Institute, taking a special interest in microscopy, and particularly in photomicrography. He soon became expert in this field, and his book *Practical Photomicrography*, written in collaboration with Mr. F. Welsh, was regarded as the standard work on this subject. Mr. Barnard was well known to many members of the medical profession, and his work at the National Institute for Medical Research on the study of applied optics gained for him his F.R.S. He worked in close collaboration with Dr. W. E. Gye for many years.

Dr. W. J. Purdy writes: With the passing of Mr. J. E. Barnard we have lost from our midst one who was perhaps the most eminent microscopist of the recent past, and in those who knew him there must arise a feeling of personal sorrow. To many of us it seemed that the outstanding characteristic of the last years of Mr. Barnard's scientific life was his singleness of purpose, his consecration to the development of the ultra-violet microscope. He early recognized the advantages to be gained by the use of wavelengths shorter than those of visible light if only the technical problems involved could be solved. He already possessed a simple ultra-violet apparatus of German origin, and, setting himself the task of improving on this model, he entered a field of research which for long remained his own. As the work progressed Mr. Barnard became more and more able to throw valuable light on various current biological problems, but in spite of considerable success in this direction he forced himself to keep such interests under control. The surveying of fields which the ultra-violet microscope began to open up could be left to others; his own special task must be the devising of ever better means of doing such work.

Mr. Barnard maintained that for him there were two associated lines of inquiry. These were the improvement of the ultra-violet microscope itself and the improvement of methods of preparing material intended for examination. He held that neither line could be pursued very far without helpful advances in the other. He did pioneer work on the internal structure of bacteria and on the nature of "inclusion bodies." He also brought forward evidence that the larger viruses at least—the larger filter-passers—were only micro-organisms which happened to be too small to be seen under existing microscopes of ordinary type—a quite artificial standard, he maintained. But still, one suspects, all this biological work had its main value for him in that it provided useful exercises in the development of the ultra-violet microscope and the methods of using it in biological studies. Indeed, he remarked on the splendid biological test objects these tiny living particles provided for him.

Mr. Barnard's singleness of purpose led to some charges of lack of co-operation with colleagues who themselves had problems demanding investigation along lines which at that time only Mr. Barnard could have followed. But it was seldom realized how much subsidiary investigation of the material itself might be necessary before microscopical investigation proper could begin, and that the evolution of his microscope might be correspondingly delayed. Though director of the Department of Applied Optics in the National Institute for Medical Research, Hampstead, Mr. Barnard preferred to remain a voluntary and part-time worker, earning his living by part-time attention to his business. He seems to have preferred to remain relatively independent in his scientific activities and thus so much the more free to direct his own course. The result is that the world now has the wonderfully efficient ultra-violet microscope he left when failing health overtook him. This microscope has now been copied in its main features and made commercially available, and its potential value is being appreciated more and more. Notwithstanding the recent introduction of the electron microscope with its surpassingly high resolving powers, the ultra-violet microscope still has a sphere of usefulness all its own. With it cells and micro-organisms can be examined in the living condition and in various wave-lengths of the ultra-violet range. Recently indeed differential absorption in the ultra-violet

range has been much used for the identification of certain organic substances whilst these are still *in situ* in the living cell.

Mr. Barnard early showed signs of his dominant interest, and he retained a vivid memory of the scene which occurred when his father discovered that leave of absence during business hours—leave which had been reluctantly granted for the study of languages conceivably useful in business—had been secretly used to attend classes in optics. He early became an active Fellow of the Royal Microscopical Society, a body whose welfare was ever afterwards very near to his heart. It fell to him to give the presidential address at the society's centenary. In this he reviewed the previous fifty years of the history of the society, a period which coincided exactly with his own period of membership. To some of us it seemed a pity that in that address he refrained from giving the inner history of the many exciting periods of the early days. Now there is no one who can do this from personal knowledge. He was an able and fascinating lecturer on his own favourite subject, but he seemed not to enjoy writing scientific papers. Towards the end of his scientific career he collected much material for a book he contemplated on the ultra-violet microscope, its structural details, and the technique of preparing objects to be examined. Unhappily this book was never actually written. Had it been ready for publication about the time of Mr. Barnard's retirement from active work it would have been of great help to those who were following on. By now much of what he discovered and taught has passed into the general body of knowledge. There remains, however, no clear summary of all that he did for the science he loved.

It is perhaps in relation to details that Mr. Barnard's genius shone most brightly, and indeed it was his technical ingenuity that proved so valuable in the development of his microscope. One seldom visited his laboratory without experiencing a fresh thrill of admiration on discovering some new simple device for overcoming some new difficulty that had been encountered in the course of his work. At one time Mr. Barnard was a keen amateur photographer, and in his laboratory at Hampstead there used to hang a photograph which had won him an "Alpine Prize." This interest in photography, of course, helped to fit him for his studies of ultra-violet light. After the first world war he played an important part in stimulating improvement in English standards of microscope design and manufacture. His mechanical and optical knowledge fitted him particularly well to act both as a destructive and as a constructive critic. The microscope he designed about this time had many valuable qualities.

Mr. Barnard was one of the last survivors of that band of kindred spirits, all amateurs, who years ago used to meet in the rooms of the Royal Microscopical Society, and he remained a true amateur to the end. Often he would recall how in those days meetings generally lasted to a very late hour, discussions being carried on with a zest and candour rarely encountered now. In the direction of the society's affairs his business knowledge and ability were invaluable, while his unassuming nature and his personal integrity, in scientific thought as in private life, were not the least of his admirable qualities.

C. O. HAWTHORNE, M.D., F.R.C.P.

Dr. Alfred Cox writes: "Men must endure their going hence even as their coming hither: ripeness is all." If ever a man of my acquaintance could claim a ripe old age it was Hawthorne. Over 91 at the end, though his physical faculties had declined, his intellect and judgment seemed to me to ripen. He was one of the finest ornaments of our Association, which has had many great figures. His achievements are well known and his departure is mourned by all who ever worked with him. Our Association gladly gave him every honour in its disposal, and Hawthorne greatly enjoyed them, but even more, I think, the real affection which he knew he had inspired. Full and successful as his career was, I have good reason to know that he felt that he had missed the position for which he was peculiarly fitted. He was a born teacher, but except for his early days in Glasgow, where his classes are still gratefully remembered by men, now old, who were his pupils, he never had the opportunity for which he longed. He told me that his greatest professional regret was that he never had a teaching-hospital appointment. He looked longingly back on his close association with Gairdner, for whom he had the greatest respect. But our Association has every reason to be grateful that he devoted his gifts to its service—his learning, his wide reading, his sagacity, his wit and humour. I should rank him very high among the many able chairmen I have known. His command of the Representative Body was masterly. The dignity and authority of the chair were never in doubt when he was in it, but he ruled quite as much by the affection all felt for him as by his authority. For many years he was the ideal chairman of one of the most difficult committees of the Association—the Central Ethical Committee. His work on the Library Subcommittee, though it never reached the limelight, was invaluable. And it should not be forgotten that he was a very active member of the original Building Committee, as is commemorated in the inscription (now almost unreadable) on the stone near the entrance gate at B.M.A. House.

I must not try to enumerate all that he did, or describe all that he was in and to the Association. Space forbids. Nor am I the right person to assess his professional status. But I know many practitioners who had great comfort and support from him as a consultant. I well remember that, being asked by an important firm to recommend "a good general physician who could be relied on for an honest opinion on the capacity for work of our higher officials," I had no hesitation in nominating C.O.H., and was not surprised when some years later I was thanked by one of the directors for helping them to secure a man in whom they had felt complete confidence.

His outside activities should not be forgotten. He did good work on the People's League of Health, especially in its pioneer work for "Safe Milk." Hawthorne would have nothing to do with less aggressive terms like "clean" or "pure" milk. We should be content with nothing less than "*Safe* Milk." He took an almost lifelong interest in the Royal Medical Benevolent Fund, and was, until he left London, the sagacious and humane chairman of its case committee. Nor should his work at the polyclinic in Chenies Street be forgotten, as I am almost afraid it is. This was real pioneer work in postgraduate medical teaching which he shared with Sir Jonathan Hutchinson and a few kindred spirits.

It was my privilege to be in close contact with him until the day of his death—personal contact when he was in London, by weekly correspondence afterwards. On the day preceding his death he dictated a letter to me which characteristically was an attempt to put me right about the proper way of dealing with that tricky term "our mutual friend." His letters were a joy. There was scarcely one which did not contain some epigram or a well-balanced sentence well worth remembering. His reading was very wide and deep. I think his favourites were the Bible, from

which he would often quote, Dr. Johnson, and Sydney Smith. In his measured sentences it was easy to trace the Johnsonian influence, and he was not displeased when one told him so. His remarkable memory enabled him at any time to produce the apt quotation or anecdote, and his *ex cathedra* speeches were eagerly anticipated and joyfully received by his audiences. He more than once delivered addresses of a popular medical character in churches—once at least in St. Martin's Church.

I was never able to draw him out on the medico-political subject which has engrossed our attention lately. He was always eager to know what was going on in Tavistock Square, and I did my best to keep him *au courant*. But he declared that he was now "out of the combat" and it was not seemly for people "on the shelf" to intervene; but no man I have ever known was a more determined upholder of professional freedom. He had his sturdy prejudices and was always ready to defend them. One of them, at one time the cause of a good deal of amusement in our Council, was his objection to any special franchise for medical women. "The qualification for election to this body," he said, "should be good honest work in the Divisions and R.B. There is no more justification for special representation of women practitioners than for practitioners endowed with the glory of red hair."

We are unlikely soon to see his like again. In spite of his age he retained active sympathy for his younger successors, and nobody was more pleased than he when he saw an opportunity to send an encouraging or congratulatory letter to an old friend. Dr. Hawthorne's wife died some years ago, but he was tended with loving care by his sister and by a faithful housekeeper who served him for twenty-four years, both of whom were with him at the end. In one of his latest letters he spoke very feelingly of the attention given to him by Dr. J. M. Anderson, of Hove.

Dr. A. G. Newell writes: I wonder how many of the students who took some of Dr. Hawthorne's classes at Glasgow remain. He had classes for each year of the medical curriculum—chemistry for first-year students, physiology for the second-year, materia medica for the third, and medicine, the eye, and medical jurisprudence for the final-year students. I took each of these, and each was "run after" and well attended. He was a born teacher, and all students appreciated his patience. Since he became a consultant I have frequently sought his excellent services, his kindly manner, and the meticulous care he took. To show his kindly and generous character, he has come from Harley Street late at night to see a case without a fee. He was a great physician and a friend of the general practitioner. Those who knew him miss his magnanimous character.

Miss Lina M. Potter writes: The death of Dr. Hawthorne will be regretted by the older generation of doctors. It is forty years since I listened to his lectures on medical jurisprudence. There has hardly ever been a year since in which I have not been grateful to him for some bit of wisdom. Looking through my notes I find this as typical of his clarity and caution: "In giving evidence—speak audibly. Don't use technical terms. Speak the truth wisely and not too well." He tried to instil into us what he described as "a medical atmosphere," which included medical etiquette and many other things besides. Subsequently when I sat under his presidency at meetings of the Representative Body I was able to appreciate other qualities. He was always strict, always fair, and never got "across the meeting." He made us laugh at ourselves sometimes but never at one another.

Dr. ALEXANDER MACINNES died at his home in Skye on October 9 after a very short illness. A native of Kylerhea, Skye, he served with the Cameron Highlanders during the 1914–18 war, and graduated M.B., Ch.B. from the University of Glasgow in 1928. For two years he acted as assistant medical officer to St. Mary's Hospital, Portsmouth, where he met his wife, then Sister Alice Boyd. He was subsequently appointed as parish medical officer to Sleat, Skye, under the Highlands and Islands Medical Service Scheme of the Scottish Department of Health. In August, 1935, he received a similar appointment as medical officer for the parish of Strath, Skye, moving then to Cairn Villa, Broadford. Dr. MacInnes had always been interested in surgery. Since he settled in Skye he had been associated with the MacKinnon Memorial Hospital, Broadford, and he was soon recognized as a surgeon of considerable ability and one on whom his island colleagues could rely. As recently as January of this year he was presented with a cheque for over £500 and his wife with a gold wrist-watch as marks of the esteem and affection of the people of Skye. Tributes were paid to their long and faithful service to the community.

W. D. M. writes: Alexander MacInnes never spared himself. He was always willing and eager to help under the most difficult and adverse conditions. An example from my own area was that of an old lady, aged 79, residing on an island. She had an acute abdomen, and the weather was stormy and the steamer unlikely to call at the pier. I phoned "Sandy" MacInnes to see what could be done. Two hours later he arrived by motor-boat, at risk to his life, with the matron from Broadford Hospital and some operating kit. On the kitchen table he performed a reduction of a volvulus safely and satisfactorily. The lady died five years later from other causes. His last 16 years' work included some notable cases: caesarean section successfully performed on a cow; a horse gored in the flank by a bull; broken spine of a dog plastered; 17-inch resection of colon; multiple duodenal perforations; and at least eight urgent mastoidectomies. Hard work and worry had of late told their tale, yet his death came as a shock to us all. I heard his cheery laugh a week before I saw him dying. He is mourned all over the island, and his funeral was one of the largest on record. About 800 people attended the service in Strath Parish Church, and over 300 people, including 14 of his colleagues, followed the cortège to Kilmore Churchyard in Sleat. A benefactor to hundreds, he was a man much loved by the people and beloved by his colleagues. We shall miss him, and to his widow and four children all extend their heartfelt sympathy.

Dr. C. Killick Millard writes: In your interesting and appreciative obituary of the late MAJOR GREENWOOD (October 15, p. 877) many aspects of his work and character are dealt with, but no reference is made to the fact that he was a firm believer in and advocate of the legalization of voluntary euthanasia. May I mention, therefore, that for many years he had been a member of the Consultative Medical Council of the Voluntary Euthanasia Legalization Society, and he was selected to put the case in favour of voluntary euthanasia in the broadcast debate arranged by the B.B.C. early this year.

Dr. H. C. Maurice Williams, in concluding his presidential address to the Society of Medical Officers of Health on October 20, said that there were still many unexplored fields for the medical officer of health in his work of acquiring an accurate knowledge of the influences, social, environmental, and industrial, which might operate prejudicially to health in his area. A closer link with industrial medicine, and investigations into the increased incidence of psychosomatic diseases, which played such a big part in present-day sickness, were necessary. An extension of the mental health services, a reduction in the accidents that occurred in the home, and the care of the aged were but a few of the many conditions that required attention. The promise of information from the Ministry of National Insurance relative to morbidity statistics should help them in assessing the local influences causing sickness.

Medico-Legal

MORPHINE FOR MOUNTAINEERS

Surgeon Fined

On October 26 proceedings were taken under the Dangerous Drugs Act against Mr. Wilson Harold Hey, a well-known Manchester surgeon.[1] Mr. Wilson Hey pleaded guilty to a charge of failing to furnish information about his supplies of morphine to a Home Office inspector. Another summons alleging obstruction of the inspector was withdrawn by the prosecution.

Mr. M. J. Jardine, who appeared for the Director of Public Prosecutions, said that on August 15 the Home Office received a letter from Mr. Wilson Hey headed "Mountain Rescue Committee." It recalled that in 1934 he had asked permission from the Home Office to include morphine in the equipment which was left at first-aid stations which had been set up by the Mountaineering Club. In this letter Mr. Wilson Hey said he understood that morphine was being used in similar circumstances in mines and on airfields. His letter concluded: "I would be extremely obliged if you could give permission; or, if you cannot do this, will you take legal proceedings against me?"

Mr. A. D. Gerrard, K.C., described how Mr. Wilson Hey had himself been a keen mountaineer for many years. He and others had been pressing for some form of rescue service in the mountains. In 1934 he came to the conclusion that morphine should be included in the first-aid equipment to be left at certain depots in mountainous districts, and he felt that "public need overrode departmental inertia." When he wrote to the Home Office in August he thought that the official attitude might have changed, as it was proposed that morphine should be used in pit accidents. Mr. Gerrard added that it was generally accepted in the medical profession that it was most important to give morphine on the spot in the case of fractures sustained while mountain climbing. Strict supervision had been exercised over the supply of morphine at the 27 first-aid stations. In the fifteen years since Mr. Wilson Hey had initiated this supply only 1½ gr. of morphine had been unaccounted for—and some part of that was known to have been used in a particular fracture case. Mr. Wilson Hey had "paid for it himself, issued it himself, and kept a record, so he knew exactly what was going on."

The stipendiary magistrate, Mr. J. Wellesley Orr, said that Mr. Wilson Hey was a pioneer of this idea, and one honoured him for it. There was no doubt that he was acting on the highest motives, but he had flouted the law. He thought it would have been better if Mr. Hey had used the very powerful influence of himself and his colleagues to approach the Home Office in a body. He was struck by the fact that nothing had apparently been done by some recognized authority to bring about a change in the law. But Mr. Hey was not entitled to defy the law.

The defendant was fined £10, with 10 guineas costs.

OVERDOSE OF NITROUS OXIDE

At an inquest held in Dublin on May 31 the jury found that the death of a woman of 38 was due to anoxaemia and cardiac failure following an overdose of nitrous oxide (*Journal*, August 27, p. 490). Subsequently the anaesthetist in this case had to appear at the Dublin District Court (October 22, p. 934). A civil action brought by the husband has now been settled.[2] The husband sued on his own behalf and on behalf of his four children the doctor concerned and the Adelaide Hospital, Dublin. It was stated for the defendants that a payment of £1,000 would be made *ex gratia* and without admission of liability. In accepting this settlement Mr. Justice Dixon allocated the money as to £700 in varying amounts to the children and £300 to the father.

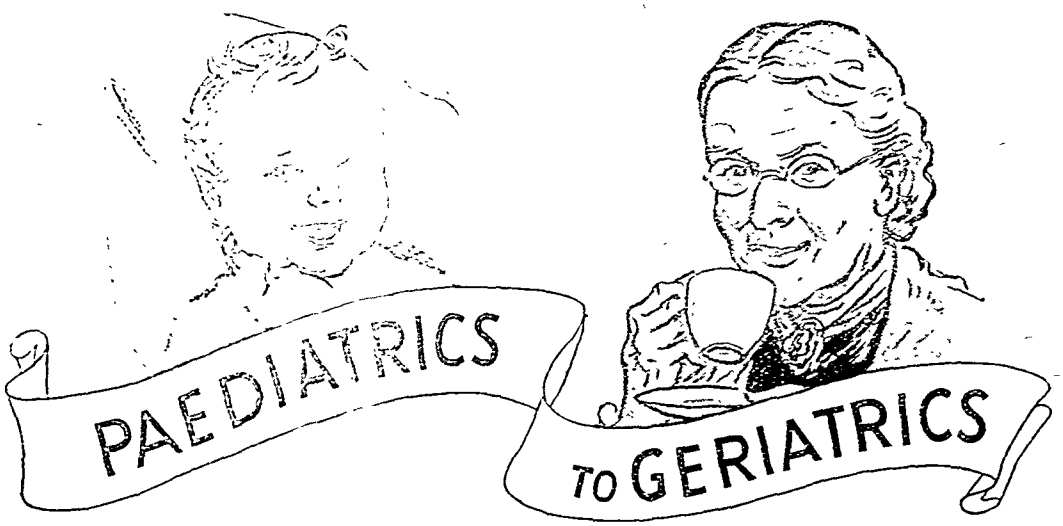
Medical Notes in Parliament

NURSES BILL

Mr. BLENKINSOP in the House of Commons on October 21 moved the second reading of the Nurses Bill. This Bill had already passed the House of Lords.

Mr. Blenkinsop expressed the regret of Mr. Bevan in being unable to introduce the Bill in the House. He said that recruitment of nurses was steadily improving and the number of both full-time and part-time nurses was increasing. The total nursing and midwifery staffs of all grades working full-time in hospitals in June, 1947, was 116,500. By June, 1948, it had risen to 118,700, and by June this year to 137,000. Part-times nurses had increased from 10,700 in June, 1947, to 17,400 in June, 1948, and 22,800 in June, 1949. There had been a gratifying increase in the number of staffed beds, but empty beds in the hospitals still showed the urgent need for more nurses.



The General Nursing Council during these difficult years had done much to improve the high standards of nursing in this country. Part of the difficulty in recruiting nurses and of the problem of those nurses who left during training was due to a conflict between the needs of training and those of staffing in the hospitals. Too often training had to take second place to staffing needs. The object of the Bill was to see that attention was given to the training of nurses. The Bill gave new responsibilities to the nursing profession through the General Nursing Council to develop the best forms of training and provide for new experiments in training where these were felt to be desirable. The Bill would also give the General Nursing Council more intimate contact with the training hospitals through the institution of regional committees. Election of nurses to the General Nursing Council, as proposed in the Bill, would give nurses a greater interest in their profession and in the Health Service as a whole. All these things in the Bill would encourage recruiting and help to stay the wastage. The strengthened Council would be supported by fourteen Standing Nurse Training Committees including representatives of regional hospital boards and teaching hospitals as well as of the General Nursing Council, the Central Midwives Board, local authorities, and educational interests. There would always be a majority representation of nurses on each regional committee.

Funds for training would be provided by the Exchequer separately and would be distributed by the General Nursing Council to regional committees. There would be a new finance committee of the General Nursing Council to watch over budgets submitted from the regions, to co-ordinate them, and to present them to the Minister. The Bill also provided for a mental nurses committee, and the training of mental nurses would now be within the ambit of the General Nursing Council.

The opportunity was also taken to provide for amalgamation of the supplementary part of the *Register* for male nurses with the general part as soon as the General Nursing Council amended its rules to admit male nurses. This recognized the fact that an increasing part was played in nursing to-day by male nurses. Last year some 20% of the nursing staffs in the hospitals of the country were male nurses. Another amendment to the 1909 Act opened the *Register* to nurses in any part of the world subject to the General Nursing Council being satisfied that training was up to British standards. The Bill did not propose that the form and contents of training should be laid down in any way by the Ministry. The Bill was a skeleton to which the professional body itself would give life. It had the approval of practically the whole of the nursing and medical professions.

Marriages and Resignations

Mr. WALTER ELLIOT said that the nursing profession contained the pick of the young women of the country, and it was not astonishing that one of the reasons for the high turnover in this industry was marriage. He objected to describing this turnover as wastage. It amounted to 15% in the voluntary hospitals, where the ratio was 15% marriage and 25% resigna-

Peptalac

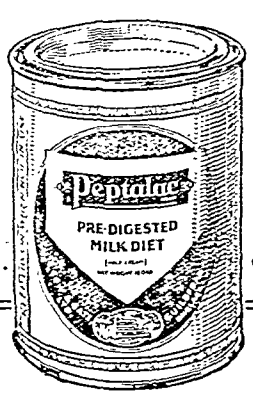
REGD

PRE-DIGESTED MILK FOOD

FORMULA	
FAT	1.8%
PROTEIN	2.4%
PREDIGESTED PROTEIN	0.8%
LACTOSE	4.1%
DEXTRINIZED STARCH	2.4%
MINERAL SALTS	0.8%

PEPTALAC, a predigested milk dietary, has been invaluable in the treatment of dietetic upsets, both of the young child, the adult, and the aged.

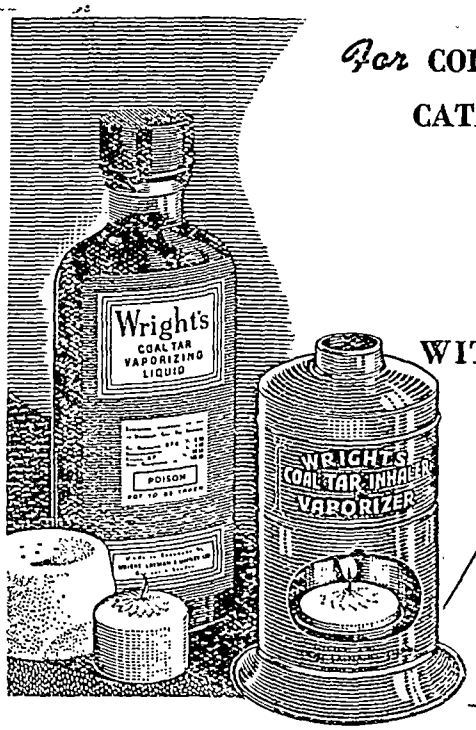
It is most palatable and is used as a dietary supplement in those suffering or convalescing from winter ills, gastric or duodenal ulcer, gastro intestinal upset and in the gastric ailments associated with old age.



PEPTALAC contains predigested protein of which a definite amount has been pancreatised to form amino acids and peptones.

PEPTALAC also contains dextrinized starch which allows of easy assimilation.

PEPTALAC is readily prepared by the addition of hot water.



PEPTALAC has superseded all forms of peptonizing powder.

PEPTALAC is a Cow & Gate Standardised Product.

tions. That was more healthy than the ratio in the sanatoria, which was 8% from marriage and 48% from resignations, or in mental institutions, where the ratio was 11% from marriage and 51% from resignations. The Bill was designed to improve the conditions to which various commissions had drawn attention and to diminish this great rate of turnover. The nursing problem still remained acute. His information was that beds staffed and occupied amounted to 398,000 and beds staffed but unoccupied to 56,000. The beds unstaffed were 52,000. The beds staffed but unoccupied were not beds out of commission. That 52,000 beds out of some 450,000 in all should be unstaffed was a weakness in the national attack upon disease. It was a sector where no assault was going forward although all the technical equipment was there for the assault to be made.

It was a grievous thing to see whole wards empty when the problem of tuberculosis was aggravated during every month in which an infectious case remained in contact with the community. The great teaching hospitals had waiting-lists of girls wishing to enrol. In addition to the prestige the interesting nature of the work was also a factor in increasing the number of girls who desired to enrol in these hospitals. He hoped the Government would indicate how the intake figures in England were moving. In Scotland these figures showed a fall in the nurses entering the profession. The entrance for the preliminary examination in Scotland was 706 in 1947 and 667 in 1948 and for the final examination 1,374 in 1947 and 1,217 in 1948. The increase in the numbers of part-time nurses was a useful development, but he did not look forward to the day when hospital nurses would pour into the gates each morning like typists into one of the great Government hospitals. He did not think that would be to the best advantage of the profession or of the patients. There was an atmosphere about nursing which induced many of those concerned in it to wish to live on the job. That of course brought in the danger of discipline degenerating into petty tyranny and the stereotyping of out-of-date conditions.

The wastage among nurses was much less in voluntary hospitals than in the local hospitals. Voluntary hospitals had solved the problems of human relationships more satisfactorily than had the local authorities. The flexibility of the private decentralized institution was an advantage compared with the more rigid rules of the State or local government institution. He thought the solution in the Bill of financial questions was a great advantage, the more so because the finances of the General Nursing Council were disordered and a deficit of £33,000 was anticipated this year.

Training at Voluntary Hospitals

Mr. MESSER, referring to the attraction of the voluntary hospital, said it was interesting in the teaching hospitals to find the pride which nurses and sisters had in their training schools. Parliament must ensure that the nurse could always take pride in the hospital where she trained. No nurse would ever say "I am proud of having been trained by the North-West Metropolitan Regional Hospital Board." An efficient ward sister was probably the most important officer in the hospital, and he hoped to see the time when their value would be recognized and they would be offered the attractions that at the moment were offered to take them away from their jobs.

For a long time he had criticized the syllabus issued for nurses by the General Nursing Council. It contained a great deal more than the practical nurse needed to learn. There was no reason why the nurse should not obtain additional qualifications in the same way as a doctor did. Was it not possible that after she was trained she could be able to get a tuberculosis certificate and other certificates dealing with children and so on?

Brigadier PETO said it would be a mistake if the teaching hospital was put on the same footing as other hospitals for nurse training and the receipt of grants. To remove the responsibility for training from the board of governors of a teaching hospital would be like removing the responsibility for the training of his men from a commanding officer. It was erroneous to imagine that by pooling the resources of all types of hospital more nurses would be available. It seemed to him that the views of the boards of governors of teaching hospitals had been overlooked by the Minister.

Mr. DIAMOND said he had been struck recently on going round a children's hospital to see the way in which the children waved and said, "Hello, Matron." When he himself had been a patient twenty-five years ago a deadly hush fell over the ward as the matron was about to approach.

Mr. HOWARD said that to suggest that the working party's report was generally accepted by the nursing profession would be entirely false.

Mrs. MANNING said so far the nursing profession had mainly looked for recruits among girls leaving secondary grammar schools. Its attention must be called to girls leaving the modern schools. Every year 82,900 girls left modern schools against 35,000 who left secondary grammar schools. Of the latter the teaching profession required 11,000. If the great teaching hospitals were brought under regional boards many difficulties would disappear.

Retaining Student Nurses

Mr. SOMERVILLE HASTINGS felt that the teaching hospitals would be better able to make their contribution in medicine and in nursing as members of the Standing Nurse Training Committee rather than as isolated from it. Much had been said in the debate about the need to obtain more student nurses, but there was a greater need for retaining them. In few schools of nursing in this country was the proportion of those who did not finish less than 40%. Nursing must be taught at the bedside, but the curriculum should be determined by the needs of the nurse rather than by the needs of the hospital. While most hospitals had 30% of trained nurses, the other 70% were nurses who had not completed their training. The sister of a ward should equal in rank the physician or surgeon in charge of the ward. The knowledge which house-physicians and house-surgeons acquired was to a large extent due to the sister of the ward, who was able to keep them on the right lines. If the training of a nurse was made more practical and intensive it could be carried out in a much shorter time. Two years' training ought to suffice for a nurse who did not want training of a degree that would fit her to become a sister or matron. He thought that nursing staffs could be diluted much more. It seemed absurd to see two trained nurses making one bed.

Mr. LINSTEAD said the difficulty in making better use of trained nurses was that in London at any rate it was as difficult to get domestic staff as to get nursing staff. There was a danger of the nursing army becoming all officers. He urged fuller recognition for the assistant nurse.

Dr. H. B. MORGAN said that when nurses went into their hospitals they should have not only a workshop but also a home. Many hospitals required modernization. Sanitation and culinary arrangements were often bad. The diet was bad and the relationship between the supervisors of the nurses and the nurses was bad. He asked that the mental side of nursing should have greater representation on the General Nursing Council. Although midwives had been long dissociated from the nursing profession they should be included in the General Nursing Council.

Government Reply

Mr. BLENKINSOP, replying for the Government, said the Bill had received a great welcome from all parts of the House. Many of the points made in the discussion should be debated in committee. At the moment more nurses were in training than ever before. In fact they had some 48,000 nurses in training to-day. In 1938, 6,700 were admitted to the *Register*, 7,900 in 1947, and 7,560 in 1948. The number of those who sat for the preliminary examination was 9,500 in 1948, 11,000 in 1947, and 13,000 in 1948. In 1948, 11,000 passed, which seemed a higher proportion than before the war. They could be satisfied that they were getting a steady though slow recruitment into the nursing profession. Teaching hospitals trained only a small proportion of nurses.

The Government felt that they needed the experience and advice of the teaching hospitals on the regional committees. Any difference between the teaching hospital and the regional committee could be referred to the General Nursing Council. The teaching hospitals could be sure they need not fear any

reduction of their standards in consequence of this Bill. In the House of Lords it had been agreed that the proposals in the Bill safeguarded the position of the teaching hospital. In considering the training needs of its area the standing committee would obviously take into consideration the needs of the training hospital.

The Ministry of Health was examining the avenues of recruitment to the nursing profession which had been mentioned by Mrs. Manning. He was prepared to consider whether legal experience would be helpful to the General Nursing Council in considering removals from the *Register*. The House would have to ensure that the statutory finance committee was a strong one and properly representative. He emphasized that the Bill was no more than an opportunity for the profession itself to take action which was urgently needed.

The Bill was then read a second time without a division and the accompanying Money Resolution was carried after Mr. Blenkinsop had explained that under it the Exchequer would have full power to grant 100% of the expenses incurred by the General Nursing Council.

NURSES (SCOTLAND) BILL

Mr. WOODBURN on October 20 moved the second reading of the Nurses (Scotland) Bill. This Bill had already passed the House of Lords (*Journal*, August 6, p. 337). He said the Bill was designed primarily to improve the training of nurses in the light of the majority report of the Working Party on Nurses of 1947. No one wished to disturb the arrangement under the 1919 Act by which direction of training and registration of nurses had been entrusted to the General Nursing Council of Scotland. The Bill proposed changes in the constitution of the Council to permit developments agreed to be desirable. It was proposed to increase the Council to 26 members—13 elected by the nurses, 11 by the Secretary of State, and two by the Privy Council. It was proposed to add a further statutory committee to the General Council to be called the Mental Nurses Committee.

The working party had reported a tendency in some hospitals to subordinate training to staffing requirements. It was considered necessary to provide special machinery for training purposes at the regional level, and nurse-training committees would be established under the Bill. The functions of these training committees would include approval of institutions for the purposes of training, and the committees were empowered to prepare schemes to improve facilities for training in their areas. Any representations they made would be considered by the General Nursing Council before the scheme was approved. the training committees would also have power to promote research and investigation into matters relating to nurse training.

The finance of training was to be separated from hospital finance generally. He believed that these improvements in the training of nurses would lead to a lower rate of wastage in training and make the profession more attractive. Clause 8 gave the General Nursing Council wide powers to admit and register nurses trained abroad. Nursing organizations in Scotland had no objection in principle to any part of the Bill.

Mr. WALTER ELLIOT and Dr. H. B. MORGAN opened the debate that followed. Mr. JOHN WHEATLEY, replying for the Government, said that he thought the Bill would improve the intake of nurses and prevent a decline of numbers. He paid tribute to the part-time nurses who had made it possible for many hospitals to carry on their work. He agreed that nothing shall be done to diminish the status and prestige of hospitals such as the Royal Infirmary, Glasgow, the Royal Infirmary, Edinburgh, the Victoria Infirmary, Glasgow, or the Royal Infirmary, Aberdeen. They should build up the status and prestige of the other hospitals.

The Bill was then read a second time without a division and the money resolution associated with it was approved.

Absenteeism in Ordnance Factories

Mr. STRAUSS on October 24 said the paid sick leave arrangements operating in the Royal Ordnance factories for industrial employees were those laid down in the scheme which applied to all Government industrial employees. The scheme, which was due for review in September, 1950, provided that after a qualifying period of six months employees might in any period of one year be granted sick leave with full pay, up to a maximum of 13 weeks, less the amount of any National Insurance benefit. Paid sick leave was conditional on production of medical certificates of unfitness obtained from a medical practitioner, who was normally the National Health Service doctor The cost of the scheme in Royal Ordnance factories for the 12 months from its introduction in September, 1948, was £296,959. The following table showed the percentage of working days lost by industrial employees in the factories on account of absence covered by medical certificates in the 12 months preceding and following its introduction:

Month	1947-8	1948-9
September	2.5	3.5
October	2.8	5.1
November	2.9	6.0
December	2.7	6.1
January	3.2	7.6
February	3.1	8.1
March	2.7	9.0
April	2.4	7.1
May	2.5	5.8
June	2.1	4.9
July	1.8	3.9
August	2.2	3.9

Mr. Strauss said he was concerned by the increase shown in these figures. This was being thoroughly investigated Appropriate disciplinary action was taken by the Ministry of Supply in cases of abuse.

Vitamin E for Heart Disease

Mr. DUMPLETON on October 24 asked what research was being carried out by the Medical Research Council into the claims made as to the effectiveness of α-tocopherol therapy for heart diseases.

Mr. HERBERT MORRISON replied that a trial of vitamin E in the treatment of angina pectoris had been carried out with financial support from the Medical Research Council. The results did not bear out the suggestion that vitamin E should be used in the routine treatment of this condition. If there was any change in the evidence, the Medical Research Council would be willing to consider it again.

Sir HENRY MORRIS-JONES said that results differing from those of the Medical Research Council had been obtained by highly reputable investigators in a clinic in Canada. Beneficial effects had been obtained from the vitamin in this country. Sir Henry urged Mr. Morrison to influence the Minister of Health to give a licence so that the product could be imported into the United Kingdom in sufficient quantities to give proper results.

Mr. MORRISON said the investigators of the Medical Research Council had taken full account of the investigations in Canada Carefully controlled attempts to repeat Dr. Shute's observations in this country and America had mostly given negative results.

Cases Referred to R.M.O.—The number of cases in which claimants to sickness benefit were referred to Regional Medical Officers for second medical opinions in the twelve months ended September 30, 1949, was 202,188. The number for the previous twelve months was 75,189.

Spectacles and Prescriptions.—Pairs of spectacles supplied for the years ended September 1, 1948 and 1949, respectively, were 4,400,000 pairs and 6,900,000 pairs. Mr. BEVAN suggested on October 27 that the supply in the following year would be at least 9,000,000 pairs. In England and Wales in the quarter ended June 30, 1949, there were about 46,000,000 prescriptions dispensed.

The Services

The Efficiency Decoration and 1st Clasp of the Territorial Army has been conferred upon Major F. V. Allen, O.B.E., R.A.M.C., T.A

The Efficiency Decoration of the Territorial Army has been conferred upon Lieutenant-Colonel H. D. Chalke, O.B.E., and Major A. D. Stoker, R.A.M.C., T.A.

Universities and Colleges

UNIVERSITY OF OXFORD

An examination will be held at Worcester College on Tuesday, January 3, 1950, for the purpose of awarding a Nuffield Medical Scholarship of the value of £100 a year, and tenable for three years. Application for entry forms should be made to the Provost of Worcester College not earlier than November 19 and not later than December 3, 1949, and the forms should be returned by December 10.

In a Congregation held on October 13 the following medical degrees were conferred:

M.D.—J. G. Widdicombe, E. A. D W. Simpson, W. W Torrance, *Nina A. Cohen.

*In absence

UNIVERSITY OF LONDON

Professor H. L. Sheehan will deliver a lecture on "Post-partum Necrosis of the Anterior Pituitary Gland" at the Westminster Medical School (Meyerstein Lecture Theatre), Horseferry Road, Westminster, London, S.W., on Wednesday, November 9, at 5 p.m. The lecture is addressed to students of the University and to others interested in the subject. Admission is free, without ticket.

Forrest Fulton, D.M., has been appointed to the University Readership in Bacteriology and Immunology tenable at the London School of Hygiene and Tropical Medicine from October 1.

The title of Professor Emeritus of Physiology in the University has been conferred on C. A. Lovatt Evans, D.Sc., LL.D., F.R.C.P., F.R.S., on his retirement from the Jodrell Chair of Physiology at University College which he has held since 1926.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At the annual meeting of the College held on October 19, the following officers were elected for the ensuing year: *President*, Mr. W. Quarry Wood; *Vice-president*, Mr. Frank E. Jardine; *Secretary and Treasurer*, Mr. J. J. Mason Brown; *Representative on the General Medical Council*, Sir Henry Wade; *Conservator of Museum*, Mr. James Norman Jackson Hartley; *Convener of Museum Committee*, Mr. John Bruce; *Librarian*, Dr. Douglas Guthrie.

The following candidates having passed the requisite examinations were admitted Fellows: S. J. Barr, A. El H. Bayoumi, C. F. A. Cummins, G. A. Fraser, S. Govindan, N. N. S. Grewal, K. S. Jones, T. Lawrie, H. A. Maslowski, M. L. Mason, W. Mathews, J. F. O. Mitchell, C. M. C. Potter, W. Recht, C. Remington-Hobbs, T. A. Sale, A. M. Shohdy, M. J. Smyth, A. Tomney, T. M. Welsh, T. W. Winchester, S. Witt.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the annual meeting of the College held on October 18, the following officers were elected: *President*, Dr. Leonard Abrahamson; *Vice-president*, Dr. P. T. O'Farrell; *Censors*, Drs. E. B. McEntee, J. Duffy, and J. G. Gallagher.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council held at the College House on October 13, with the President, Sir William Gilliatt, in the chair, the following were admitted to the Membership of the College: A. B. Backus, Jessie E. C. Baird, T. E. C. Barns, Anusya Bhagat, D. H. Blakey, V. Y. Bockner, S. C. Bose, M. B. Bruce, R. C. Cummin, Mona M. Davin-Power, R. G. Denniss, H. Doberman, T. Dougray, L. W. D. Drabble, C. T. F. Ealand, G. K. Emsley, G. M. Evans, J. J. Foley, P. S. Gardner, G. W. Garland, H. K. B. Geiser, Elizabeth Gilbertson, Marie P. S. Grant, G. T. Hammond, J. C. Harvey, J. Henderson, J. A. Henderson, D. W. Hendry, R. W. Hutchinson, E. W. Ilangantileke, E. P. Jones, F. G. E. King, J. M. King, E. W. Kirk, Joan E. M. Lambert, D. Latto, J. G. Lawson, F H. Leckie, E. M. Leyland, J. W. F. Lumsden, J. M. McCracken, I. MacGillivray, H. N. Mansfield, S. M. Medine, W. G. Millar, R. Moolan-Feroze, Ll. O. Morgan, M. R. Neely, F. C. R. Picton, J. G. Reynolds, N. A. Richards, S. Riterband, T. W. Roddie, C. A. Samad, E. M. Sandler, Olive C. Sandys, J. W. F. Scrimegeour, Sita Sen, J. G. Shelton, Norah P. Sherlock, J. A. McC. Smith, Doreen M. J. Stracey, A. B. Swarbreck, J. L. Taylor, S. D. Tewary, J. Watson, G. F. J. Williams.

The address of Nursing Services Branch of the Ministry of Labour and National Service has been changed to: 3, St. James's Square, London, S.W.1 (Telephone: WHItehall 5484).

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 15. [No. 41

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1949 (a)	(b)	(c)	(d)	(e)	1948 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Rate per 1,000 total births (including stillborn)			13					29		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ *The number of deaths from* poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications in the week ended October 22 were: poliomyelitis 385 (418), polio-encephalitis 29 (45). Figures for the previous week are in parentheses. It is hoped that the decline will be maintained, but it is to be expected that the figures will remain higher than usual at least until the end of the year.

Multiple cases (poliomyelitis and polio-encephalitis together) occurred in the following counties: London 66 (68), Bedford 3 (7), Berkshire 6 (4), Chester 8 (7), Cornwall 4 (6), Cumberland 2 (7), Derby 5 (2), Dorset 3 (10), Durham 3 (4), Essex 32 (39), Gloucester 12 (21), Hertford 6 (11), Kent 26 (33), Lancaster 25 (32), Leicester 13 (10), Lincoln, Lindsey 7 (0), Middlesex 19 (18), Norfolk 8 (8), Northampton 2 (4), Northumberland 9 (3), Nottingham 9 (11), Somerset 10 (9), Southampton 13 (10), Stafford 12 (3), Surrey 16 (14), East Sussex 2 (4), West Sussex 2 (2), Warwick 9 (16), Westmorland 2 (0), Wiltshire 4 (8), Worcester 2 (1), East Yorks 3 (3), North Yorks 3 (3), West Yorks 47 (48), Glamorgan 6 (4), Monmouth 4 (1).

Discussion of Table

In *England and Wales* there were increases in the notifications of scarlet fever 220, acute poliomyelitis 78, measles 66, and acute pneumonia 42, with decreases in the incidence of dysentery 111 and whooping-cough 33.

A slight increase in the incidence of scarlet fever was recorded in most regions; the only notable increase was 79 in Lancashire. The chief centres of scarlet fever in this county were Liverpool C.B. 63 and Manchester C.B. 61.

The local returns for measles showed little change; the largest rises in incidence were Durham 44 and Norfolk 30. Notifications of diphtheria were fairly constant, and the chief centres of infection were Liverpool C.B. 16 and Birmingham 11. In the incidence of whooping-cough, the largest changes were a decrease in Yorkshire West Riding 37 and increases in Lancashire 25 and London 20.

Of the 13 cases of paratyphoid fever 8 were notified in Lancashire. Notifications of dysentery fell from 217 to 108 in Lancashire; the largest returns during the week were Ince in Makerfield U.D. 31, Abram U.D. 20, Hindley U.D. 20, and Liverpool C.B. 18. Other large returns for dysentery were Durham 11 (Hetton U.D. 9) and London 10. Of the 29 cases of cerebrospinal fever 9 were notified in Birmingham C.B.

In *Scotland* there were increases in the notifications of scarlet fever 41, acute primary pneumonia 31, whooping-cough 21, and diphtheria 10. A rise of 13 in the notifications of diphtheria occurred in Glasgow. The increased incidence of scarlet fever was confined to the western area; in the remainder of the country there was a slight fall in incidence.

In *Eire* an increase of 33 in the notifications of measles and a decrease of 14 for scarlet fever were recorded. In Waterford C.B. there was an increase of 21 in the notifications of measles. For the fourth consecutive week a slight decrease was reported in the incidence of diarrhoea and enteritis.

In *Northern Ireland* a decrease of 19 in the notifications of scarlet fever was the chief feature of the returns. This fall was contributed by Belfast C.B.

Quarterly Returns for England and Wales

During the June quarter the birth rate was 17.7 per 1,000, compared with 18.8 for the second quarter of 1948. The infant mortality was 30 per 1,000 live births and was the lowest ever recorded for any second quarter, being 1 below the rate for the June quarter of 1948 and 17 below the average for the second quarters of the ten years 1938–47. The death rate was 11.1 compared with 10.2 for the preceding second quarter and an average of 10.7 for the second quarters of 1943–7. Deaths attributed to acute poliomyelitis and polio-encephalitis numbered 28. There were 20 cases of smallpox notified, with 5 deaths.

Quarterly Returns for Northern Ireland

The birth rate during the second quarter was 22.9 per 1,000, 1.3 below the average of the five preceding second quarters. Infant mortality was 38 per 1,000 registered births and was 17 below the average of the corresponding quarters of the five preceding years. The death rate was 11.2 per 1,000, being 0.8 below the average of the five preceding second quarters. Deaths due to the principal epidemic diseases numbered 68, and included 29 from influenza, 21 from diarrhoea and enteritis, 10 from whooping-cough, and 4 from diphtheria. Deaths from pulmonary tuberculosis numbered 169 and from other forms of tuberculosis 48; these figures were 36 and 29, respectively, below the average of the second quarters of 1944–8.

Vital Statistics

In reply to a question in the House of Commons on October 27 the following table was circulated.

	Death Rate per 1,000 Total Population	Birth Rate per 1,000 Total Population	Infant Mortality Rate per 1,000 Related Live Births
1933	12·3	14·4	63
1938	11·6	15·1	53
1948*	10·8	17·9	34
1949			
March quarter*	15·0	17·4	40
June quarter* ..	11·1	17·7	30
Sept. quarter* ..	9·2	16·7	26

* Provisional

The expectation of life at birth in 1938 was 61.40 years for males and 65.84 for females. In 1945 it was 62.56 for males and 68.58 for females.

Week Ending October 22

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,909, whooping-cough 834, diphtheria 92, measles 1,052, acute pneumonia 317, cerebrospinal fever 24, acute poliomyelitis 385, acute polio-encephalitis 29, dysentery 154, paratyphoid fever 18, typhoid fever 6, food-poisoning 88.

Medical News

Commonwealth Fund Fellowships

Fellowships tenable in the United States are offered to British subjects by the Commonwealth Fund of New York. The fellowships, which are not only medical, are in four categories: (1) 20 ordinary fellowships are open to candidates who (*a*) are over 23 and under 35 years old on September 1 of the year of award, and (*b*) have not worked or studied in any educational or research institution in the United States for one or more academic years. Candidates in the United Kingdom and Northern Ireland must be university graduates. (2) Five home Civil Service fellowships are open to candidates holding permanent appointments in the higher ranks of the Civil Service in Britain (three for administrative grades and two for technical and professional grades). (3) Five Dominion Civil Service fellowships are open to candidates who hold appointments under the Governments of Australia, New Zealand, and South Africa. (4) Two Colonial Civil Service fellowships are open to candidates who hold appointments under the Governments of the British Colonies, protectorates, and trust territories. Particulars may be obtained from the secretary of the Committee of Award, 35 Portland Square, London, W.1.

B.M.S.A. Report

The British Medical Students Association has issued its annual report for the year 1948–9, which gives a summary of the association's many activities at headquarters and in the regions. Copies may be seen in the medical school libraries, and are held also by B.M.S.A. representatives in the medical schools.

French Award

The Médaille de la Reconnaissance Française has been presented to Mr. Arthur Miller.

Eric Guttman Memorial Trust

A trust in memory of the late Eric Guttman was founded recently by his widow, Dr. Elizabeth Rosenberg. Its purpose is: (*a*) To further the development of the Guttman-Maclay collection of pictures and books related to art and psychiatry; (*b*) to help the medical staff of the Bethlem Royal and Maudsley Hospitals (other than staff of consultant status) to attend scientific meetings and conferences, and (*c*) to furnish loans to young psychiatrists to further their psychiatric training. Further particulars may be obtained from: The Trustees, Eric Guttman Memorial Trust Maudsley Hospital, Denmark Hill, London, S.E.5

New School of Occupational Therapy

The Derby School of Occupational Therapy was opened on October 27 by Dr. H. Balme of the Ministry of Health Rehabilitation and Resettlement Department. The school is the seventh of its kind in the country and the first which forms part of the National Health Service. Miss I. Fretwell, M.A.O.T., formerly head occupational therapist to the United Sheffield Hospitals, is the principal. The course lasts three years, and will be carried out in connection with the Derby School of Arts and Crafts. Practical experience will be provided in the general, orthopædic and mental hospitals in the area. There will be at least [illegible] when the school is in full operation. The scheme for the formation of this school was first submitted to the Derby County Mental Health Committee in 1946. A meeting of representatives of the Derby Corporation and Derbyshire County Council Hospitals and Education Committees, the local authorities' hospitals, and the medical profession endorsed the proposals and advice was obtained from the Association of Occupational Therapists. In view of the imminence of the "Appointed Day" (Health Act) the scheme was referred to the Sheffield Regional Hospital Board and approved. After July 5 [illegible] subcommittee consisting of representatives from each of the four Derby Area Hospital Management Committees, the local authorities' education committees, and the medical profession was appointed to administer the school.

Wessex Rahere Club

The second annual dinner of the Wessex Rahere Club was held at the Spa Hotel, Bath, on October 15. Sir James Paterson Ross was the guest of honour and the chairman was Mr. C. E. Kindersley. The secretary reported that membership of the club, which was open without subscription to all Bart's men in the South-west, was now well over 100 and increasing steadily. Professor R. A. Brocklehurst was unanimously elected chairman for 1949–50. It was agreed that the third annual dinner would be held in Bristol on October 21, 1950. The toast of the hospital was proposed by Mr. C. E. Kindersley and linked with the name of Sir James Paterson Ross. In reply, Sir James outlined the present plans for the reconstruction and development of St. Bartholomew's Hospital, and mentioned particularly the progress which was being made at the Charterhouse site and in the provision of a residential hostel. He emphasized that the quality of the students entering the hospital was as high as ever. It is hoped that any Bart's men who are interested, and are not yet in touch with the club, will notify their whereabouts to the honorary secretary, Mr. A. Daunt Bateman, 3, The Circus, Bath.

The Sherrington Society

A new society named after Sir Charles Sherrington has been formed at Liverpool by a group of students who have taken an honours degree in physiology and are continuing their studies in clinical medicine and dentistry. The aim of the society is to bring together clinicians and those who study the basic medical sciences. The first meeting was held on October 19, when Sir Henry Cohen addressed an audience of about 300 people on "Some Aspects of Pain." The next meeting will be held on November 9 at 7.30 p.m. in the physiology lecture theatre of the University and will be addressed by Professor A. C. Frazer, of Birmingham, on "Studies of Normal and Abnormal Fat Absorption in the Human Subject."

American Scholars

Five American scholars have recently arrived in this country under the auspices of the United States Educational Commission to study various aspects of medicine for about nine months. It is the wish of the Commission that they should have opportunities of meeting as many British men and women as possible of similar interests. Their names and where they are working are as follows: Dr. R. W. Russell, Institute of Psychiatry, London University; Dr. E. Sachs, Jun., National Hospital, Queen Square, London; Dr. J. E. Thompson, Nuffield Institute for Medical Research, Oxford University; Dr. R. Driver, Edinburgh University; and Miss J. L. Brand, London School of Economics.

Ministry of Food Model By-laws

The Ministry of Food has just issued to local authorities a series of model by-laws intended to supplement measures already in force under the Food and Drugs Act, 1938. They replace the series prepared by the Ministry of Health in 1939 and should help to secure the observance of sanitary and cleanly conditions in the handling, wrapping, and delivering of food. Local authorities and trade associations were consulted in the preparation of these model by-laws, and their provisions cover personal hygiene, cleanliness and good order of equipment, cleanliness of wrapping materials, and the deposit and removal of refuse.

Medical Golfing Society

The following prizes were won at the autumn meeting of the Medical Golfing Society at Sandwich: Canny Ryall Cup, by Dr. H. McCann; Rolf Creasy Salver, by Mr. E. B. Whittingham; Lindsay-Rea Cup, by Mr. T. A. Torrance; Veterans Cup, by Mr. W. McK. H. McCullagh; Milsom Rees Cup, by Dr. M. B. Stungo.

Paediatrician in Portugal

Professor Alan Moncrieff, Nuffield Professor of Child Health in the University of London, is lecturing in Portugal under the auspices of the British Council. He returns on November 10.

Prospective Conservative Candidate

Dr. A. Genevieve Rewcastle has been chosen prospective Conservative candidate for West Willesden. This is Dr. Rewcastle's first Parliamentary candidature. During the war she served in the W.R.N.S., being the only woman to attain the rank of surgeon lieut.-commander.

COMING EVENTS

Adlerian Society

A meeting of the medical section of the Adlerian Society of Great Britain will be held at 11, Chandos Street, Cavendish Square, London, W., on Thursday, November 10, at 8 p.m., when Dr. Morris Robb will lecture on "Psychotherapy of Psychotics." The discussion will be opened by Dr. R. Dennistoun Scott.

Scientific Films

The London Optical Practitioners' Branch of the Association of Scientific Workers is holding an evening of scientific films of special interest to optical and medical practitioners at Friends' House, Euston Road, London, N.W., on Thursday, November 10, at 7.30 p.m. The admission charge is 2s.

The Victor Horsley Memorial Lecture

The Victor Horsley Memorial Fund, which was raised in 1920 to commemorate the services of Sir Victor Horsley to science and the Empire, is devoted to the giving of a lecture triennially in London entitled the "Victor Horsley Memorial Lecture." By invitation of the trustees (the Presidents for the time being of the Royal Society, the Royal College of Surgeons of England, and the British Medical Association, the Senior Physician of the National Hospital, Queen Square, and Mr. Stanley G. Robinson, son-in-law of Sir Victor Horsley) the eighth lecture will be delivered by Sir Hugh Cairns, Nuffield Professor of Surgery, University of Oxford, in No. 1 Lecture Room, University College Hospital Medical School, University

Street, Gower Street, London, W.C.1, on Thursday, December 8, at 5 p.m. The title of the lecture is "Disturbances of Consciousness with Disorders of the Brain Stem," and the chair will be taken by Dr. F. M. R. Walshe, F.R.S. Admission to the lecture is free on presentation of visiting-card.

Manchester Royal Infirmary Old Residents' Club

Members are asked to note that it is proposed to hold the next reunion of old residents on Saturday, March 25, 1950, at Belle Vue, Manchester. Further details will be notified later. Members should notify any recent change of address to the Honorary Secretary, Old Residents' Club, Manchester Royal Infirmary.

SOCIETIES AND LECTURES

Monday

LONDON UNIVERSITY.—At University College (Chemistry Theatre), Gower Street, London, W.C., November 7, 5.15 p.m., "*The Chemistry of the Transuranics and Other Newly Discovered Elements*," by Professor H. J. Emeléus, F.R.S.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—November 7, 4.45 p.m., "*Bacterial Toxins*," by Dr. W. E. Van Heyningen.

Tuesday

CHELSEA CLINICAL SOCIETY.—At South Kensington Hotel, 47, Queens Gate Terrace, London, S.W., November 8, 7 for 7.30 p.m., "*A Stipendiary Magistrate*," discussion to be opened by Mr. W. B. Frampton.

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, November 8, 5 p.m., "*The Costoclavicular Syndrome*," by Professor F. A. R. Stammers.

ILLUMINATING ENGINEERING SOCIETY.—At the Lighting Service Bureau, 2, Savoy Hill, London, W.C., November 8, 6 p.m., *Specialized and General Lighting in Hospitals*," by Messrs. M. W. Peirce and D. J. Reed. A discussion will follow.

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—November 8, 5 p.m., "*Histopathology of the Skin*," by Dr. I. Muende.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Postgraduate Medical School of London, Ducane Road, W., November 8, 3 p.m., "*Kidney Function*," by Professor K. J. Franklin.

Wednesday

CAMBRIDGE UNIVERSITY.—At Addenbrooke's Hospital, Cambridge. November 9, 2.30 p.m., "*The Teaching Hospital and the General Practitioner*," by Dr. L. B. Cole.

LONDON UNIVERSITY.—At Westminster Medical School (Meyerstein Lecture Theatre), Horseferry Road, Westminster, London, S.W., November 9, 5 p.m., "*Post-partum Necrosis of the Anterior Pituitary Gland*," by Professor H. L. Sheehan.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW, 242, St. Vincent Street, Glasgow.—November 9, 5 p.m., "*The Relation of Hypertension to Renal Circulation*," Dr. John Burns Lecture by Professor J. Trueta.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—November 9, 3.30 p.m., "*Skin Ailments and the Public Health*," by Dr. W. J. O'Donovan.

SOCIAL PSYCHOTHERAPY CENTRE, 7, Fellows Road, London, N.W.—November 9, 5 p.m., "*Instructional Group Psychotherapy, II*," by Dr. E. N. Snowden.

SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP.—At Imperial Institute, South Kensington, London, S.W., November 9, conversazione. 6 p.m. Informal reception by Sir Harry and Lady Lindsay and Mr. A. L. Bacharach (chairman of the society) and Mrs. Bacharach; 6.45 p.m., film of Food Group on tour in France, June, 1949. Admission by ticket only.

SOUTH WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, London, S.W., November 9, 8.30 p.m., "*Hoarseness as a Symptom*," by Mr. W. I. Daggett.

Thursday

HONYMAN GILLESPIE LECTURE.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, November 10, 5 p.m., "*Amputations, with Special Reference to the 'Phantom Limb' Phenomena*," by Mr. G. H. Stevenson.

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—November 10, 5 p.m., "*Leukoplakia: Lichen Sclerosus of the Ano-genital Region*," by Dr. H. J. Wallace.

INSTITUTE OF PHYSICS: MANCHESTER AND DISTRICT BRANCH.—At College of Technology, Manchester, November 10, 6 p.m., "*Recent Advances in the Physiology of Colour Vision*," by Professor H. Hartridge, F.R.S. Joint meeting with the Illuminating Engineering Society.

LIVERPOOL MEDICAL INSTITUTION.—November 10, 3 p.m., "*Physiological Reactions of Bone and the Problem of Non-union Fractures*." Hugh Owen Thomas Memorial Lecture by Sir Reginald Watson-Jones.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, 17, Bloomsbury Square, London, W.C.—November 10, 7.30 p.m., "*The British Pharmaceutical Codex, 1949*," by T. C. Denston, B.Pharm., Ph.C., F.R.I.C.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.—November 10, 5 p.m., "*Sarcoidosis, with Special Reference to the Lung Changes*," Bradshaw Lecture by Dr. J. G. Scadding.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—November 10, 5 p.m., "*Visceral Actinomycosis and its Treatment*," Bradshaw Lecture by Mr. V. Zachary Cope.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—November 10, 4.30 p.m., lecture-demonstration: "*Psychiatry*," by Dr. D. Curran.

TORQUAY AND DISTRICT MEDICAL SOCIETY.—November 10, 8.30 p.m., clinical discussion.

Friday

MAIDA VALE HOSPITAL FOR NERVOUS DISEASES MEDICAL SCHOOL, Maida Vale, London, W.—November 11, 5 p.m., clinical demonstration by Dr. Blake Pritchard.

ROYAL INSTITUTE OF PHILOSOPHY, 14, Gordon Square, London, W.C.—November 11, 5.15 p.m., "*Scientific Concepts and Synthetic Philosophy*," by Mr. S. E. Toulmin.

ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh.—November 11, 8 p.m., "*Unorthodox Healing—An Assessment*," by Mr. R. C. Tyldesley.

ROYAL SANITARY INSTITUTE.—At Huddersfield Technical College, November 11, 10 a.m., "*Recent Regulations Relating to Milk*," by Dr. John M. Gibson.

SOCIETY OF CHEMICAL INDUSTRY: FINE CHEMICALS GROUP.—At *King's College (Chemistry Lecture Theatre), Strand, London*, W.C., November 11, 7 p.m., "*The Chemistry of Antihistamine and Related Drugs*," by Dr. D. W. Adamson, M.Sc. A discussion will follow.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—November 11, 5.15 p.m., "*Transmission of Excitation in Nerve and Muscle*," by Dr. Bernhard Katz.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—At Miller Hospital, Greenwich High Road, London, S.E., November 11, 8.30 p.m., "*Some Conditions Affecting the Parotid Gland*," by Dr. R. S. Bruce Pearson.

Saturday

BIOCHEMICAL SOCIETY.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., November 12, 11 a.m., 281st meeting. Symposium: "*The Biological Oxidation of Aromatic Rings*."

APPOINTMENTS

Lieutenant-Colonel F. M. Lipscomb, F.R.C.P., has been appointed Physician and Surgeon to the Royal Hospital, Chelsea.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—*House-physicians (Junior Registrar Grade)*, T. J. Rendle-Short, M.B., B.Ch., M.R.C.P., D.C.H., E. H. Back, M.B., B.Ch., M.R.C.P., R. G. Mitchell, M.B., Ch.B., M.R.C.P., D.C.H. *House-surgeon (Junior Registrar Grade)*, R. J. Alcock, M.B., B.Ch. *Resident Medical Officer, Tadworth Court (Registrar Grade)*, Joan P. D'Arcy, M.B., B.Ch., B.A.O. *Assistant Resident Medical Officer, Tadworth Court (Junior Registrar Grade)*, Gwendoline Hewitt, M.B., B.S., D.G.O., D.C.H.

BARREN, G. F., M.D., Consultant Chest Physician in the King's Lynn and West Norfolk Area, East Anglian Regional Hospital Board.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Clift.—On October 21, 1949, at Croydon, to Dr. Dorothy (née Newell), wife of A. F. Clift, F.R.C.S., a sister for Priscilla and Theo—Mary Elizabeth.

Crittenden.—On October 26, 1949, to Stella (née Jolly), wife of Dr. Kenneth Crittenden, The Woodlands, Kings Bromley, a daughter—Rosemary Jean.

MARRIAGES

Affleck—Barrow.—On October 17, 1949, in London, Ian Affleck, O.B.E., M.R.C.S., L.R.C.P., of Kearsley, Farnworth, Lancs, to Yolande Barrow, of Cogny, Rhône, France.

Green—White.—On October 21, 1949, at St. Bodfan's Church, Aber, Caernarvonshire, David Mitchell Green, M.B., Ch.B., of 16, Ancrum Road, Dundee, to Elizabeth White, M.B., Ch.B., of Aber, Caernarvonshire, and 6, South Oswald Road, Edinburgh.

Pearse Williams—Wright.—On October 15, 1949, at Epsom, Thomas Pearse Williams, M.D., F.R.C.P., of 50, Harley Street, London, W., to Joyce Christina Wright, C.S.M.M.G., younger daughter of the late J. J. Muir Wright and of Mrs. Muir Wright, of Bucklands, Kingswood.

DEATHS

Bateman.—On October 21, 1949, at 199, Shooters Hill, London, S.E., James Alexander Bateman, M.B., Ch.B.

Crichton.—On October 21, 1949, at 31, Hillhead Street, Glasgow, W., David Macquorn Rankine Crichton, M.B., C.M., J.P., of Burgh House, Maryhill, Glasgow.

Harrowell.—On October 27, 1949, at 113, Tadcaster Road, York, Francis William Harrowell, M.B., Ch.B., formerly of Beeston Hill, Leeds, and late of Great Haywood, Staffs.

Harvey.—On October 25, 1949, at Chircheby House, Kirkby Malzeard, Ripon, Yorks, Robert George Mills Harvey, L.R.C.P.&S.I., aged 85.

Heasman.—On October 17 1949, at 18, Sea Road, Boscombe, Bournemouth, Frank Heasman M.R.C.S., L.R.C.P., aged 84.

Herriot.—On October 20, 1949, at 8, Castle Terrace, Berwick-on-Tweed, Thomas Pearson Herriot, M.D., D.P.H.

Moritz.—On October 18, 1949, at Stoney Hill, Walkerburn, Scotland, Arnold Moritz, M.B., B.Ch., late of Melbury Court, Kensington, London, W., aged 77.

Mallam.—*On October 23, 1949, at Danetree, Compton, Berks, Dalton Mallam*, M.R.C.S., L.R.C.P., of Irstead, Neatishead, Norfolk.

Morton.—On October 16, 1949, at 15, Fothringham Road, Ayr, John Kerr Morton, M.B., C.M., J.P., aged 84.

Needham.—On October 24, 1949, in London, Sir Richard Arthur Needham, C.I.E., D.S.O., M.D., F.R.C.S., Colonel I.M.S., Ret., aged 71.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Hard Water

Q.—*Is there any evidence that excessively hard water has a deleterious effect on the human body? Apart from increasing the hardness of a soap solution, would the fact that it contains soluble salts have any effect?*

A.—The relative merits of hard and soft water is an old one. Consumers are aware of the hardness of water by reason of its soap-destroying properties and where bicarbonates are present to any extent by the deposition of scale in kettles. It may well be that such effects have drawn attention to the harder waters, whereas soft waters have been associated with the various [illegible] from time to time been ascribed to their low mineral calcium, and a predisposition to dyspepsia [illegible] is attributed to hard water. Some workers [illegible] that the nature of the substances giving hardness influences the effects upon consumers [illegible] magnesium salts are more harmful than [illegible] daily requirement of calcium by the human [illegible] of a gramme, while that of magnesium [illegible] salt a gramme. The normal daily consumption [illegible] hard water would not supply these quantities [illegible] no question of the body's receiving a surfeit of [illegible] through a hard water supply.

Investigations have been made to determine the relative states of health of large communities receiving hard as distinct from soft waters, but no evidence has been found that the general health has been affected one way or the other. Very soft waters may be plumbo-solvent, very hard waters are domestically inconvenient, and the consensus of opinion is that the ideal hardness for a public supply is about 100 parts per million. It may be added from experience that, except where a supply is unmistakably very soft, consumers often do not know whether their water supply is hard or not. In more than one area people have complained of the hardness of the supply when in fact it has been softened.

Underground supplies near the coast are sometimes subject to infiltration of sea-water. The susceptibility of individuals to salt in water varies somewhat, but a concentration of 700 parts per million is just detectable by most people. In some parts of Essex there is as much as 1,400 parts per million, but the local population apparently do not notice it or, if they do, have become accustomed to it.

Softened Water

Q.—*Are there any dangers in the use of artificially softened water for drinking purposes during pregnancy and for young children? Should the diet be supplemented in any way?*

A.—When water is softened, calcium is removed. Hard water used for drinking and cooking may supply 0.2 g. of calcium per day. The loss of this amount of calcium is unimportant unless the amount supplied by the rest of the diet is very low; a pint of milk supplies 0.7 g. Softening of water has no other action that might affect health.

Ultra-violet Lamp in the Home

Q.—*Is it possible, by an ultra-violet lamp used in the home, to retain a summer tan through the winter? Is it worth while doing, and would it confer any immunity to colds, influenza, and other winter infections?*

A.—The ultra-violet lamps used in the home have mercury-vapour emitters. The pigmentation caused by this spectrum is of a greyish tinge and is not the same as the tan caused by the solar spectrum or the carbon arc. Thus it is not possible to retain a true tan by the winter use of a lamp in the home. There is no scientific evidence that exposure to ultra-violet irradiation will confer immunity to colds, influenza, or other winter infections. A thorough investigation into this was carried out by the Industrial Health Research Board, whose report (No. 89) was published in 1946. This report was summarized in the *Journal*, and was the subject of a leading article on June 8, 1946 (p. 882).

Neostigmine in Myasthenia Gravis

Q.—*Where does neostigmine exert its action? What dosage is given for an early case of myasthenia gravis, and should administration be discontinued during remissions? Are any toxic or other undesirable effects likely to follow a long-continued course of treatment?*

A.—Neostigmine, like eserine, of which it is a synthetic analogue, acts at the neuromuscular junctions by inhibiting cholinesterase, which inactivates acetylcholine in the body. It thus increases the effect of acetylcholine liberated at the nerve endings. The exact cause of myasthenia gravis is unknown. The disease may be due to a deficiency of acetylcholine, to an excess of cholinesterase, or to the liberation of some curare-like poison. The dosage of neostigmine in myasthenia depends on the severity of the condition at the moment, and not on whether the case is in the early stages or long-standing. The drug is usually given by the mouth in 15-mg. tablets. Mild symptoms may be controlled by as little as two or three tablets a day, while severe symptoms may demand as much as 12 tablets in the 24 hours. In emergencies 1 to 2 mg. should be given by subcutaneous injection. There is no point in continuing the medication during a complete remission. Toxic effects—which are relieved by atropine—are intestinal colic, bradycardia, collapse, sweating, salivation, and miosis. They are due to overdosage or to unusual sensitivity to the drug and not to long-continued administration, as the effects of neostigmine are not cumulative.

Interpreting Laboratory Reports

Q.—*The result of a serum test is reported as follows: "Salmonella typhi (O and H), negative 1 in 25; Proteus OX19, OX2, and OX K., negative 1 in 50." What does this imply?*

A.—The absence from the blood of demonstrable antibody to the H and O antigens of *Salmonella typhi* suggests that the individual has not recently (say within the past two to three years) been inoculated against typhoid or suffered from a clinical attack of the disease. He might, of course, be in the early stages of infection, since antibody does not usually develop in the first week. A negative finding, however, does not necessarily mean that the individual is susceptible to typhoid fever. Some patients do not develop any demonstrable agglutinin during an attack, and in a proportion of inoculated persons the antibody titre may drop quickly to a low level; but this need not imply that the individual has not developed, or has lost, resistance to typhoid. Indeed, the function of humoral antibody as a protection against enteric infection is not easily defined. It is known that antiserum containing O or O+Vi antibody is protective against experimental infection in mice, but why does the patient with demonstrable antibody in the blood develop a relapse, and why do recently inoculated and reinoculated troops sometimes succumb to infection? On the other hand, among a susceptible civilian community exposed to the risk of infection, as by drinking contaminated water, only a proportion get a clinical attack. The serum of a chronic typhoid carrier may give negative reactions to the H and O antigens, but usually reacts positively (in a titre of 1 in 10 or higher) to the Vi antigen.

As much, or more, caution must be observed in interpreting a negative response to *Proteus OX19, OX2,* and *OX* K. in relation to rickettsial infection. In some severe cases of typhus, as well as in mild cases, the Weil-Felix test may show a very low titre to the *Proteus* antigen; in other patients this antibody quickly falls below demonstrable level. Yet all these patients are likely to have a high degree of resistance to further

infection by typhus, although not to other rickettsial infections, such as scrub typhus or Q fever. It should also be noted that, in a variable proportion of sera from normal persons with no history of infection or inoculation, antibodies to the *Salm. typhi* and *Proteus* antigens may be demonstrated in titres ranging from 1 in 20 to 1 in 100.

Vasomotor Rhinorrhoea

Q.—*What investigations should be undertaken in a case of persistent vasomotor rhinorrhoea? For three years a patient has suffered from a practically continuous severe vasomotor rhinorrhoea. There is a profuse discharge of mucus, and the need for continuous nose-blowing interferes with work and is a social handicap, besides being extremely fatiguing. He underwent an operation for deflected septum at the age of 17. The nares are patent during remissions; the sinuses are not infected; there is no seasonal incidence, and no evidence of sensitivity to a specific allergen. Causes of exacerbation are mechanical, neurogenic, and psychogenic. Complete but temporary relief is given by antihistamine agents applied locally and also by vigorous outdoor exercise. Is there any prospect of a cure?*

A.—The prospect of cure depends on finding the cause, which is often difficult. The appearance of the mucous membrane of the nose might give a guide to the cause. The nasal discharge should be examined on several occasions, during exacerbations and if possible during remissions, for eosinophil and polymorphonuclear leucocytes. If eosinophils only are found, the condition is allergic and the allergens are of the extrinsic type—for example, inhalants such as house dust, feathers, foods, and drugs. If eosinophils and polymorphs occur together, the condition is due either to a superadded infection of a basic allergic oedema (extrinsic in type) or to an allergic reaction to an infection. If only polymorphonuclear leucocytes are found, the condition is infective in origin, although it has been suggested that some of these apparently primary infective cases are really secondary infections on a boggy mucous membrane produced psychogenically.

In the allergic cases inhalants are the common allergens, and skin tests are thus often helpful. They are best carried out and their significance assessed by a competent worker in this field. Foods and drugs account for only a small proportion of cases of allergic rhinitis. In the absence of a personal or family history of allergy, with no eosinophils or pus cells in the nasal discharge, and with negative intracutaneous skin tests, a psychogenic cause should certainly be sought.

Fowls and Cantharides

Q.—*Has it ever been established that fowls which have ingested cantharides and have subsequently been killed and eaten have caused fatal effects in man?*

A.—No. We can find no reference to evidence that fowls which have eaten cantharides, and have subsequently been killed and eaten, have caused fatal accidents in man.

Frequent Attacks of Petit Mal

Q.—*What is the best treatment for a girl of 8 who has 20 to 50 attacks of petit mal daily? Attacks can be brought on by "over-breathing." While bathing she has no attacks and rarely when carrying out vigorous exercise. Does this type of case require any treatment other than the usual anti-epilepsy drugs?*

A.—Electroencephalography should be carried out, if this has not already been done, in order to ascertain the type of dysrhythmia present. An abnormal rhythm of the wave-and-spike variety would be an indication to try "tridione," but no other type of rhythm is likely to respond to this drug. In addition to the ordinary anticonvulsant drugs, it would be worth while trying belladonna in doses of 5 to 10 minims (0.3 to 0.6 ml.) of the tincture three times a day, and also amphetamine sulphate in doses of 2.5 mg. two or three times a day, the last dose being taken not later than tea-time. A ketogenic diet is sometimes successful, but it is probably impracticable outside a hospital to-day. Petit-mal attacks of such frequency are often described as pyknolepsy. There is doubt whether this is a nosological entity, but in some such cases, although the attacks respond little, if at all, to treatment, they cease spontaneously.

Washing out the Stomach

Q.—*In a case of non-corrosive poisoning, what advantage has gastric lavage over apomorphine plus plenty of salt and water?*

A.—When gastric lavage is used it is possible to be certain that the stomach has been thoroughly washed out by looking at the washing. Plenty of salt and water plus a dose of apomorphine would sometimes be just as efficient, but it might not always be so.

NOTES AND COMMENTS

Jealousy in a Child.—Colonel N. J. C. RUTHERFORD (Farnham, Surrey) writes: With reference to the question and answer on the above subject ("Any Questions?" August 27, p. 495), I have recently observed the same situation. A sturdy little boy aged 4 showed almost virulent dislike of his sister aged 2 years. It got so bad that neighbours grew alarmed and warned an anxious young mother. The boy would deliberately charge into his sister and knock her over; and when he thought himself unobserved he would make violent attacks on the little girl, who, incidentally, was a particularly gentle and shy child. There was no question of disability in the mother, but the father, being a Regular officer, was much away from home. The mother was firm in a way, but never used any form of corporal punishment to control the boy. Then the father came home for a longish spell of leave, and the situation changed rapidly. The boy was not smacked, but was shown plainly that ill-treatment of his sister meant isolation from the other members of the family and a marked air of general displeasure (somewhat spoilt by the little girl victim, who invariably made up to the naughty one during such sessions). Going to children's parties was beneficial, as sometimes the family spirit was aroused and the boy had to stand up for his sister against comparative strangers, which he did in no uncertain fashion, and acquired a protective spirit. In this case there is no doubt that a grandfather displayed like characteristics in his youth. I cannot see psychotherapy having much influence in this case. The boy is essentially masculine, full of pluck, has a mind of his own, is no fool, and will one day be a natural leader. It is just a phase and will pass away as the years grow.

Hunterian Society.—Dr. CLEMENT FRANCIS writes: The president and council of the Hunterian Society much appreciate the notice of the Hunterian party (October 15, p. 868). But there is one error in the opening sentence which I should be grateful if you could perhaps correct. The annual party is in *addition* to, and not *instead* of, the annual dinner which is to be held at Grosvenor House on February 16, 1950. The mistake has probably arisen from the fact that two years ago we were unable, because of rationing problems, to hold our usual annual dinner.

Treatment of Stings.—Captain J. F. GOW, I.A.M.C., writes from Kankinara, West Bengal: I have read correspondence off and on regarding bee stings and jelly-fish stings and I do not remember ever having seen vinegar and salt mentioned as a treatment. The treatment consists in taking about one teaspoonful of common salt and adding to it an equal quantity of vinegar and rubbing in the mixture well at the point of the sting. The relief is instantaneous, and no inflammation results. This treatment should be carried out as soon as possible after the individual has been stung.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Britmedads, Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medsecra, Westcent, London.*

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY NOVEMBER 5 1949

THE SECRETARY REPORTS

CONFERENCE OF LOCAL MEDICAL COMMITTEES

The Conference of Representatives of Local Medical Committees managed in one day to dispose of a relatively formidable agenda and to escape the criticism voiced at some recent Representative Meetings that the time factor has prevented adequate discussion. Last week's Conference was no exception, possibly because the representatives were unanimous in reaching some of the more important decisions. The representations on behalf of general practitioners in the Service made to the Ministry as long ago as March 3 this year remained unanswered when the Conference met, and the chairman of the General Medical Services Committee was speaking for representatives from all parts of the country in his strong condemnation of the Ministry's "go slow" tactics.

The Ministry undertook to complete certain investigations "reasonably soon" after the G.M.S. Committee submitted its case some seven months ago. The next step was the receipt from the Ministry in mid-August of a formidable document of some 240 pages of statistics of general practitioner income, which the committee on examination criticized as unreliable and inaccurate in parts. This involved substantial revision of the document, and it can be understood that this takes time. What could not be understood by the Conference was the apparent inability of the Ministry to correct the inaccurate calculations made at the inception of the Service in determining such factors as the size of the Central Pool. One incontrovertible fact is that the number of general practitioners entering the Service proved to be higher than the number which had been estimated for the purpose of this calculation.

The Conference unanimously deplored the delay on the part of the Ministry in dealing with the matter and passed a second resolution, again unanimously, that, as the proper calculation of the amount of the Central Pool, including an adjustment for any increase in the number of doctors, can be undertaken without awaiting the redraft of the Ministry's document on general practitioner remuneration, it be demanded of the Ministry that this step be taken now in agreement with representatives of general practitioners.

Health Centres

It was reported to the Conference that a vigilant watch was being maintained on the development of plans for health centres. Local medical committees have been asked to use their influence to prevent the hasty establishment of undesirable types of health centre.

After consideration of the implications of the clause in the N.H.S. Amending Bill to enable general practitioners associated with health centres to attend private as well as public patients there, the Conference endorsed the decision of the G.M.S. Committee not to oppose this proposal. At the same time it proposed certain measures to protect the position of the doctor who transfers his practice to a health centre. The view was expressed that, during the experimental period, in any area in which a health centre is to be opened an essential preliminary is that no doctor should be allowed to open a surgery (including a surgery at his residence) within an agreed area surrounding the health centre for a specified period before and after the opening of the centre. This rule is not intended to apply to principals practising in the health centre or to a doctor who at the commencement of the specified period had premises in the area from which he practised and was on the executive council list.

Certificates of Unregistered Practitioners

In moving a resolution on this subject a representative stated that in his town the Ministry of National Insurance office had undertaken to consider "on their merits" certificates of incapacity given by unregistered practitioners. A few days ago a statement in more positive terms was issued by the British Health Freedom Society informing its members that "the Ministers of Health and National Insurance had issued a directive that certificates of *bona-fide* unorthodox practitioners shall be accepted for payment of sick benefit." The Conference is informing the Minister that it strongly disapproves of any certificate of incapacity given by an unregistered practitioner being considered by the Ministry of National Insurance —even "on its merits."

The Prescription Charge

There are still no details available of the proposed method of giving effect to the Government's decision to make a charge of not more than 1s. (except in the case of old-age pensioners) for each prescription under the National Health Service. The Conference recorded its opinion that in no circumstances whatever should a doctor be required to become an agent to collect a Government charge on prescriptions.

General Practitioners and Hospital Work

Three weeks ago certain important passages in a Ministry circular were commended in this column. In that circular—R.H.B.(49)132, which appeared in the *Supplement* of October 15 (p. 168)—the Minister advises regional hospital boards in reviewing plans for the change of use of cottage hospitals to consider the continued provision of beds in the charge of general practitioners, including maternity beds in the charge of general-practitioner obstetricians. The Conference regards this as sound and acceptable advice and is suggesting to local medical committees that they should take every opportunity of securing its implementation in their areas by regional hospital boards and hospital management committees. A number of other resolutions were passed with the object of bringing the general practitioner into closer association with hospital work.

A Busy Year

This selection of some of the more important decisions of the Conference overlooks the vast amount of steady spade-work which the G.M.S. Committee has undertaken during the first 15 months of the Service. Some indication of its continued "plugging away" to remove anomalies and to secure improved terms and conditions of service is reflected in the committee's Annual and Supplementary Reports published in the *Supplement* of August 27 (p. 99) and of October 1 (p. 150). The subjects dealt with, to take a few examples, include mileage, temporary residents, basic salary, inflation of doctors' lists, vaccination and immunization, the filling of practice vacancies, certification, various dispensing and prescribing points, maternity services (including fees for miscarriages), superannuation, assistants, treatment of seamen, emergency treatment following dental operations, partnership shares, refresher courses, income tax, and the Special Inducement Fund.

That the Conference was sensible of the vigilant work being carried on was evidenced by the warm vote of confidence which it accorded to the G.M.S. Committee and by its great appreciation of the work already done by the committee.

SPECIAL INDUCEMENT FUND

The Ministry of Health has been asked to arrange for the balance of the Special Inducement Fund to be distributed among general practitioners who are able to substantiate claims on hardship grounds as a result of the introduction of the National Health Service. The Ministry has agreed on principle, and the details will shortly be under discussion.

AUSTRALIAN HEALTH SERVICE

The Australian Minister for Health, Senator McKenna, has stated that, in view of the recent High Court judgment that Section 7a of the Pharmaceutical Benefits Act is invalid, the free-medicine scheme will be on a voluntary basis (*The Times*, October 26).

This Act required doctors to use a Government prescription form when prescribing free medicine. The action had been brought in the High Court by the Federal Council of the B.M.A. in Australia.

PAYMENT OF REGISTRARS IN TEACHING HOSPITALS

Representations have been made to the Minister that certain medical schools would prefer to contribute towards the salaries of registrars employed in teaching hospitals. This matter has been discussed with the University Grants Committee, which has confirmed the following resolution by the Medical Advisory Committee:

That the committee do not regard it as generally essential, on educational grounds, that universities should contribute to the salaries of registrars employed in teaching hospitals. They would, however, consider it appropriate that any university which desired to make such a contribution up to 50% of the registrars' salaries should be permitted to do so if its financial circumstances allow.

The Minister will make whatever arrangements may be preferred by a particular university or medical school for contributions towards registrars' salaries. It is not suggested that any initiative should be taken by a board of governors to obtain contributions. But, should a university or medical school intimate to the board that it desires to contribute an amount of up to 50% of the salaries of registrars employed in a teaching hospital, the board should agree. The precise proportion should be a matter of arrangement between the board of governors and the medical school or university concerned.

REGISTRATION OF OPTICIANS

EVIDENCE INVITED

The Intra-departmental Committee on the Statutory Registration of Opticians (*Supplement*, October 1, p. 149) will consider evidence relevant to its inquiries from interested bodies or persons. It has already invited evidence from some; others wishing to put their views before the committee should submit written memoranda to the secretary of the committee, Ministry of Health, Whitehall, London, S.W.1.

FRIENDLY SOCIETY CERTIFICATES

The General Medical Services and Private Practice Committees have considered the request of a deputation of the National Conference of Friendly Societies that practitioners should not charge for medical certificates of incapacity requested by aged members of Friendly Societies who are not entitled to sickness benefit under the National Insurance Act and therefore do not ask for National Insurance certificates.

Both committees are sympathetically inclined to the view that in these circumstances practitioners should not charge for such certificates provided the society supplies a form for the doctor's signature.

CENTRAL CONSULTANTS AND SPECIALISTS COMMITTEE (SCOTLAND)

The Central Consultants and Specialists Committee (Scotland) held its first meeting of the new Session on October 20. Mr. I. Simson Hall was re-elected chairman of the committee with Dr. T. Murray Newton as deputy chairman.

The following members were appointed to represent the committee on the Central Consultants and Specialists Committee for the coming year: Professor L. J. Davis, Dr. I. D. Easton, Dr. J. G. M. Hamilton, Mr. I. Simson Hall, Dr. J. B. King, Mr. N. J. Logie, Mr. W. S. Mack, Dr. T. Murray Newton, Dr. A. R. Wilson, and Dr. J. H. Wright.

General Practitioners and Hospitals

The committee discussed the proposal to form a joint subcommittee with the General Medical Services Subcommittee (Scotland) to consider problems affecting general practitioners in relation to hospitals under the National Health Service. Many members expressed the view that the new administrative arrangements, far from leading to the desirable integration of the profession, were resulting in a growing separation of the interests of specialists and practitioners. In the interests of medicine as a whole it was essential that this tendency should be checked. The committee therefore agreed to the immediate formation of a subcommittee capable of co-ordinating the views of both specialists and general practitioners.

Distinction Awards

The committee was unanimously against the suggestion that consultants and specialists should be required to apply for distinction awards, but considered that the proposed regional committees should remain in being and review regularly (probably annually) the qualifications of all consultants in the region from the point of view of special distinction awards.

Any new holder of an appropriate hospital appointment should be asked to complete a statement of his qualifications. No new entrant to the specialist service would then have reason to suppose that any claim he might have to a distinction award had been ignored by the regional committee through lack of information.

Part-time Appointments

Attention was drawn to the action of certain regional hospital boards in appointing or proposing to appoint whole-time officers in charge of hospital departments where these posts had hitherto been held by senior consultants on a part-time basis. In specific cases quoted by one member of the committee, the regional hospital boards in question had declined to reconsider their decision to make the posts whole-time, no option being given to the senior consultant in the area to accept the appointment on a part-time basis.

The chairman pointed out that this policy of the regional hospital boards, if pursued, would nullify the provisions of the Amending Bill designed to give effect to the Government's declared intention not to require all specialists to be employed whole-time. The committee felt very strongly that immediate action should be taken, and referred the matter to the Joint Committee for Consultants and Specialists (Scotland) with a request that it be taken up with the Department of Health for Scotland as one of urgency.

Other Business

The committee gave general approval to the proposals submitted by the Executive Committee of the Central Consultants and Specialists Committee for the establishment of an independent fighting fund for consultants.

The committee then considered a protest from consultants in the Western Region regarding the wording in the contracts offered to clinical teachers. The consultants thought that the phrase "so long as you continue to hold your appointment as clinical teacher from the university" was tantamount to granting an outside body the power to dismiss a consultant from employment with the regional hospital board. The chairman reported that, having anticipated similar difficulties, the South-Eastern Regional Board had, with the approval of the

Department of Health, altered the offending phrase to read "in association with your teaching appointment with the university."

Attention was drawn to a document which had been issued to certain clinical teachers in conjunction with their contracts, in which it was stated that, in the event of the termination of a teaching appointment, the regional hospital board would issue a new contract to the consultant concerned. While it was doubtful if an undertaking in this form would be legally enforceable, it was felt that it did go some way to safeguard the position of the affected individual. The secretary was therefore instructed to request the Department to invite all regional hospital boards to issue the document to all clinical teachers in contract with them. The representatives of the Western Region were advised to approach their regional hospital board once more with a request that the phraseology of the contracts to clinical teachers be altered as had been done in the South-Eastern Region.

It was reported that the report prepared by the special subcommittee which had been appointed to investigate the position of medical superintendents in Scotland under the N.H.S. had been the subject of a discussion between the Scottish Joint Committee and officials of the Department of Health. A further discussion is to be held when the Department has prepared a revised scale of remuneration for the medical superintendents in Scotland.

HEARD AT HEADQUARTERS

Flank Attacks

After reading in the papers the other day that regional hospital boards are being "packed with Socialists" we were not surprised to see a report the following day that "belted earls and whissy magnates" have crept on to the boards. The former opinion was attributed to the Conservative Party's *Weekly News Letter*, the latter to Dr. Ian Gilliland, chairman of the executive of the Socialist Medical Association. These views were apparently expressed independently and not in repartee, which seems to suggest that the boards are a fairly representative spectrum of political colour. That is as it should be in a country which prefers to take its politics in mixtures rather than by injections of pure synthetic products. The vocabularies of political allegation still seem to favour the Socialist. Belted earls, as we all know, are regarded with suspicion the whole world over, except perhaps in the House of Lords, whereas the hiss of "Socialist" has lost much of the arresting thrust that it had 50 years ago. Incidentally, a fortune undoubtedly awaits the first man to invent a whisky magnate.

Good Chairmanship

Headquarters has seen some excellent chairmen—a task demanding physical as well as mental energy—and Dr. Walter Jope, presiding over the Conference of Representatives of Local Medical Committees, started the day with some sound advice: "Can you hear me? Now, if any representative intends to speak let him take his place in the queue at the back of the platform. If while waiting there he finds that his point has been made by speakers in front of him, let him go back to his place without putting it again; but if there is really a point which he thinks should be put and has not been put by others, let him make it succinctly, with due regard to the time limit. But I must warn him against the dreadful fate which overtakes anyone who comes too frequently to the microphone—they make him chairman of the Conference."

Questions Answered

Purchase Tax

Q.—*I propose to buy an electric floor-polisher for use on the surgery and waiting-room floors, and also a refrigerator, which will be used partly for storing drugs and sometimes blood. Am I entitled to exemption from purchase tax?*

A.—There is no exemption from purchase tax for either of these articles even when used for the purposes stated.

LOCAL MEDICAL COMMITTEES' CONFERENCE

ACTION ON REMUNERATION SETTLEMENT DELAY

The Annual Conference of Representatives of Local Medical Committees was held in the Great Hall of B.M.A. House, London, on Thursday, October 27. Dr. W. Jope (Blantyre, Lanarkshire) presided. Almost every committee in Great Britain was represented. The principal discussions took place on matters arising in the annual and supplementary reports of the General Medical Services Committee, published in the *Supplements* of August 27 (p. 99) and October 1 (p. 150), which were introduced by Dr. S. Wand (Birmingham), chairman of the committee.

Some discussion took place on a proposed change in the date of the Annual Conference, the committee holding that if it were held in June it would facilitate the work of the committee in the early autumn, and also, the date being nearer that of the Annual Representative Meeting, it would make for better co-ordination between the two conferences. Representatives from Worcester, Buckinghamshire, Gateshead, and other constituencies, however, desired that the date of the Conference should remain in October, and this proved to be the view of the majority of the Conference (86 to 72).

The First Year of the Committee

Dr. Wand, who was cordially received, introduced the reports of the General Medical Services Committee. The committee, he said, had had a strenuous year. The agenda of its monthly meetings rarely contained fewer than 60 items, and sometimes as many as 100. As general practitioners they had lost no ground in their discussions with the Ministry, and they had made some gains, but none were easily won. The Minister at the beginning, when urging them to come into the Service, had said that if there were unresolved difficulties the sharp edges would be smoothed over by subsequent discussion. In almost every case, however, when they had made a gain they had had to fight hard.

In the field of midwifery a certain number of improvements, relating to attendance at miscarriages, emergency midwifery, and so on, had been obtained. At an earlier conference the position of the rural practitioner had been strongly brought forward, and they had now obtained for the rural practitioner an extra half million of new money and £200,000 from the Special Inducement Fund, making the total sum in the mileage pool £2 million. There could be no doubt that the man in the easy rural area got too much in comparison with his colleague in the more difficult rural area, and it was evident that men in what had been called the "mountain and lighthouse" cases would require special treatment. The committee had set up a Health Centre Subcommittee, which had been considering in particular the protection of the doctor who wished to take his practice in such a centre. The interminable delay in the discussions with the Ministry over remuneration would be the subject of resolutions to come before the Conference. It was most difficult to overcome the "go slow" movement in a Government department.

A very noticeable feature of the first year's experience was the changed attitude of the patient—the demanding attitude, the attitude which required the doctor to do certain things. Lay people in high places who should know better often seemed most unwilling to recognize the difficulties under which doctors were working. In Birmingham there had been published in the press what took place at a recent meeting of the executive council when a doctor had the temerity to say that their waiting-rooms were so congested with trivial cases that it was difficult to find time to attend adequately to the others, and he was thereupon "pulled to pieces" by the lay members. If the lay members of executive councils would not understand their problems, it was only to be expected that the public generally would not understand them or make doctors' lives any easier. They were suffering in this respect from the success of the Government's propaganda before the inception of the Act.

"We are fighting for more than money," said Dr. Wand; "we are fighting for status. The downgrading of the general practitioner during the last twelve months has been a most disturbing thing. The receipts in general practice compared with those of other professional sections in the Service have made the position of the general practitioner almost a laughing-stock. The exclusion of practitioners from midwifery work in hospitals has helped to push us down the ladder. The Government has now issued a document to regional hospital boards (*Supplement*, October 15, p. 168) which indicates a somewhat changed tone in Government and higher circles, and if this is acted upon there will be an improvement in this respect. The grading of general-practitioner specialists has been regrettable in many areas, where the type of hospital has determined the grade rather than the ability and qualifications of the man himself."

Dr. Wand concluded his opening speech with remarks in high appreciation of Dr. E. A. Gregg's long service as chairman of the old Insurance Acts Committee.

The Remuneration Issue

Dr. Wand went on to make a statement on the delay on the part of the Ministry in replying to the representations made to it as long ago as March 3 on the determination of the amount of the general practitioners' central pool. He said that on first approaching the Ministry on this subject they were told that it was necessary to make certain investigations, which would be completed "reasonably soon." Not until August was the document received—an immense document entitled "Doctors' Remuneration Tables," running to 240 pages. The committee was immediately called together, and after examining the document an interview with the Ministry took place within a week or two of its receipt. The document on close examination was found to be entirely unreliable and misleading. It showed the amounts of money which had been paid to doctors, but it disregarded such things as deflation of lists and also the effect of partnerships in which the money paid to one of the partners might be out of all proportion to his share of the profits of the practice. The Ministry had desired to publish the findings of that document. The committee took no exception to the publication of an accurate document, but they had been able to pull this document to pieces in a manner in which probably no Government document had ever been dealt with before. The Ministry then promised to look into the matter further, and on October 19 a letter was received from Sir William Douglas, Secretary to the Ministry, stating:

"We are looking carefully into the points raised at our last meeting. This has involved a good deal of research, and I am afraid, to my regret, it will not be possible to arrange for a further meeting before your Annual Conference."

"We are tired of this delay," Dr. Wand continued, "this 'go slow' method, which can be regarded as an unfair weapon in the light of the knowledge they must have; and, although we are faced at the moment with an embarrassing position occasioned by the financial crisis, I for one see no reason why we should not be able to determine as from July 5, 1948, what was the proper amount in the 'kitty' having regard to the Spens report." ("Hear, hear.")

He proceeded to move the following resolutions, which were formulated at a special meeting of the General Medical Services Committee the previous day:

That this Conference deplores the delay on the part of the Ministry of Health in replying to the representations made to it as long ago as March 3, on the determination of the amount of the practitioners' central pool which should have been made available from the inception of the National Health Service.

This was carried unanimously.

The second resolution was:

That as the proper calculation of the amount of the central pool, including an adjustment for any increase in the number of doctors, can be undertaken without awaiting the redraft of the Ministry's document on general practitioner remuneration it be demanded of the Ministry that this step be now taken in agreement with representatives of general practitioners.

Dr. P. Y. Lyle (Southport) said that his was called an "over-doctored" area, and it might be supposed that the doctors retained considerable income from private practice; but that was not so, for 93% of the population were on the lists, and the position for doctors who had been in receipt of fair incomes was very serious.

Dr. W. D. Anderson (Glasgow) said that in the suburban areas of his city, where doctors had very much smaller lists than in the industrial sections, unless something was done immediately to relieve the situation the smouldering resentment amongst practitioners would endanger the success of the scheme.

Dr. Harriette Woodhouse (Middlesex) said that the general practitioners in her area were "absolutely tired of waiting." It had been said that doctors in industrial areas, who were reasonably well off under the scheme, would not support any decisive action. It was for the rest of them to see that their colleagues in industrial areas stood by them in getting proper conditions for doctors in suburban and country districts. The remuneration of general practitioners suffered greatly in comparison with that of dentists and opticians. Why should general practitioners be the cheapjacks of medicine? Was it not time they used the only weapon the Minister understood and themselves faced the sacrifice involved? The situation was in their hands if they stood together. She called upon the assembly for united action.

Dr. A. H. Weston (Middlesex) wished to see a little real leadership in the General Medical Services Committee. There was an old saying in the Army, "Whatever you do you will probably be wrong." But here, if they did nothing, the, would certainly be wrong.

Dr. Wand pointed out that one word in his resolution was stronger than had been used before—the word "demanded."

The resolution was carried unanimously.

Dr. Noy Scott (Devon and Exeter) had an amendment which was taken as a rider to Dr. Wand's motion. It introduced the words "at the earliest possible date, when the financial state of the country permits." He said that, however just their claim might be, they had no right to place themselves above every other section of the community. The effect of his rider was to demand full recognition forthwith, but to delay the financial implementation of it in the immediate future. He put this forward as a practical resolution as opposed to a pious resolution which carried them nowhere.

Dr. J. A. Ireland (Shrewsbury) said that this rider assumed a position which did not exist. The question of an increase of pay in other walks of life was on the basis of an increase rate of pay in the past. In this case there had never been an agreed rate of pay between the profession and the Ministry. The rider had no relevance.

Dr. H. H. Goodman (Newcastle) said that nobody would accuse the doctors of being non-cooperative in a state of national emergency, but something must be done to help the position of doctors who had relied on private practice in the past, and he believed it was the intention to use the £16.5 million or part of it to help doctors with very small lists—people who could not wait until the national economy had been adjusted. The profession was not asking for an increase of remuneration, but that the pool established at the inception of the Service should be properly composed.

Dr. Noy Scott's rider was, in the words of the chairman, "lost almost unanimously."

Dr. D. Saklatvala (West Bromwich) moved to instruct the committee to report on the probable effect on the distribution of general practitioners' incomes (and their relationship to the Spens recommendations) of the apparent decision of the Ministry to reduce the number of patients per doctor in all areas where the average exceeds 3,000, and in view of the expressed opinion of the Medical Practices Committee that the number of doctors in an area was not adequate if the average list per principal was substantially in excess of 1,600.

Dr. J. E. Darlow (Holland, Lincolnshire) supported this motion on the experience of his own area.

Dr. J. A. Pridham, a member of the Medical Practices Committee, said that Dr. Saklatvala had seemed to convey an insinuation that the Medical Practices Committee was an

instrument of the Ministry to reduce the numbers on doctors' lists. That was not so. The committee was not an instrument of policy. It was not for it to say what was a desirable area. It simply made it known in what areas the number of patients to the doctor was high and in what areas low.

Dr. Saklatvala said that he was quite clear that the Medical Practices Committee was not responsible for policy.

His motion was carried.

Rural Practitioners and Mileage

Dr. A. G. Holman (Norfolk) asked the Conference to express the opinion that the proposed mileage adjustment scheme was unjust in that several essentially rural practices were classified as semi-rural, and inasmuch as total mileage was ignored and only mileage over two miles taken into consideration. When, owing to housing considerations, a doctor had to live on the periphery of his area of practice, he got a much greater number of mileage units than he did if he lived in the centre, but the actual number of miles he covered in a year remained the same. This seemed rather unjust to the doctor who lived in the centre of the area.

Dr. J. C. Pearce (chairman, Rural Practitioners Subcommittee) pointed out that the principle of the mileage scheme was not to cover the expense of running a car, but was intended as a yardstick in order to measure the necessity of the rural practitioner with a view to assuring him an average income comparable with his colleague in the town. He did not think it feasible to argue from individual cases, but the present method was, in his view, reasonably effective.

Dr. H. J. Browne (Staffordshire) maintained that the total mileage fund was still not adequate. A good practice in the country with a list of 2,500 should be equal in income to a first-rate industrial practice.

Dr. Wand thought that rural practitioners should await the publication of the Doctors' Remuneration Tables before comparing rural and urban remuneration. Those tables were in some ways extraordinarily revealing. The whole purpose of the adjustment had been to make a fair comparison between practitioners, not in order that they might take money out of a bottomless pit, but so that they could divide the money available fairly amongst themselves. The Rural Practitioners Subcommittee was *satisfied in the light of present evidence*—and would revise its opinion in the light of future evidence—that the money was now being divided as justly as human endeavour could ensure it.

The Norfolk motion was lost.

Temporary Residents

Dr. J. T. Baldwin (Lothians and Peebles) moved to amend para. 44 of the Annual Report on the question of temporary resident credits, which he desired should be given only in those cases "in which medical *advice and/or* treatment has been given" (his motion being to insert the words which are italicized). There was no definition of the word "treatment" in the terms of service. It should be made clear that advice was a form of treatment.

Dr. Wand said that the word "treatment" obviously included "advice," but the purpose of the paragraph in the report was to deal with a situation such as arose when a mother on holiday with her children had occasion to see the doctor about one member of the family and brought along all the other members. There was nothing at present to stop the doctor signing temporary resident forms for each member of the family. If the word "advice" were included it would be an encouragement to doctors who contemplated such action.

The motion was lost.

The Isle of Wight suggested that the submission of Forms E.C.7 and 8 to a patient's own doctor served no useful purpose, whereas a detachable slip on Form E.C.19, bearing a diagnosis, which the patient could hand to his doctor, would be of clinical value. Dr. F. E. Gould asked whether there were not enough forms to fill up already, and whether this could not be left to ordinary common sense as between doctors. An Isle of Wight motion on the subject was lost.

Basic Salary

Dr. A. Owen (Lancashire) moved to instruct the committee to consider the question of basic salaries in all its aspects with a view to reopening discussion of the subject with the Minister. Basic salary was paid out of the local pool and administered by the executive council, but any man who was refused basic salary had a right of appeal to the Ministry. He mentioned an instance of a doctor who had retired and gone to live at the seaside, and then undertook practice in the N.H.S., making a claim for basic salary which was turned down but allowed on appeal to the Minister. In Lancashire they felt that if they were to pay the piper they should call the tune, or if the Minister insisted on calling the tune the Government, and not the practitioners' pool, should pay.

Dr. A. T. Lowden (Hampshire) said that executive councils were being overridden by the Minister, who compelled basic salary to be paid.

Dr. Wand accepted the motion for consideration by his committee.

Filling of Vacancies

A motion by the Isle of Wight, which was accepted, called for closer contact between the Medical Practices Committee and local executive councils, together with local medical committees, before the filling of vacancies. This was accepted.

Dr. G. D. Thompson (Lancashire) moved:

That the appointment of a successor to a practice declared vacant should be made by the local executive council in consultation with the local medical committee without submission to the Medical Practices Committee.

Too much centralization was a bad thing. The present system gave rise to so many unavoidable delays that it was the more important to eliminate any avoidable ones. It took a minimum of six weeks to fill a vacancy. He had personal knowledge of a practice in which a death vacancy occurred, and as it happened, owing to special circumstances, the successor was in the practice within a fortnight, yet within that fortnight half the practice disappeared among other doctors or because people were left untraced. If that could happen in a fortnight, what could happen in six weeks?

Dr. J. H. Francis (Nottingham) said that the delay was nearer three months than six weeks. There were cases within his knowledge in which the Medical Practices Committee had overruled the local executive council and appointed another practitioner altogether, thereby causing local resentment.

Dr. J. A. Pridham said that the Lancashire motion would require an amendment of the Act. The Act had placed on the Medical Practices Committee the task of selecting doctors for vacancies. But any amendment was unnecessary. Delay need not occur owing to any action of the Medical Practices Committee. There were certain delays at the executive council end. The Medical Practices Committee had addressed a letter to executive councils pointing out the best way in which vacancies could be filled—namely, by the local executive council, in consultation with the local medical committee, interviewing the applicants and sending up a short list. If the job was done properly the Medical Practices Committee within a very few days endorsed the local recommendation and the vacancy was filled, but the job was not always done properly at the local level.

Dr. A. Campbell (Lancashire) said that unless they were careful they would become completely centralized, and all doctors would be chosen by the Medical Practices Committee. Dr. A. V. Russell (Wolverhampton) said that in his area two death vacancies occurred, and there was a delay of three months before appointment. Dr. Harriette Woodhouse (Middlesex) said that it was obvious that the Minister was out to get all the power into his own hands; the Medical Practices Committee was his creation and responsible to him. Was it not time to keep control in the hands of local bodies?

Dr. Frank Gray (London) said that the present position was that when the local executive council and the local medical committee had made a recommendation it went to the Medical Practices Committee, and then there might be an appeal to the Minister. If they merely cut out the Medical Practices

Committee they threw the whole power into the Minister's hands. When the profession put up its representatives for the Medical Practices Committee everyone was aware that they were liable to be shot at, but the General Medical Services Committee was satisfied that Dr. Pridham and his colleagues had done their difficult job well.

Dr. I. D. Grant (Glasgow) said that a recent conference of interested bodies in Scotland had expressed the view that it was desirable that the actual appointment to vacancies should be made by the local executive councils, after consultation with local medical committees, and that the Medical Practices Committee should be an appeal committee instead of the Minister. Dr. Wand said that the words "in consultation with the local medical committee" would mean a great deal in some areas and nothing at all in others. He believed that the Medical Practices Committee was doing as fair a job as it was possible to do. One point of great importance which was secured from the beginning was that if a doctor took a partner, proper notice having been given, that partner, on the other leaving the practice, came automatically into succession. He was sure that that method of entering into practice had not been sufficiently carried out. If it were, a number of these delays and difficulties would be avoided.

Dr. Thompson, in reply, said that he had made no accusations against the Medical Practices Committee, but he thought its position rather futile at the moment. In most cases it acted merely as a rubber stamp.

The Lancashire motion was lost.

On the motion of Dr. J. A. Ireland (Shrewsbury), seconded by Dr. W. Woolley (Bristol), the Conference expressed the opinion that the Medical Practices Committee, when considering appointments to practices, should invite a representative of the local medical committee to be present for consultation.

Dr. Grant said that in Scotland, in the event of disagreement, the Medical Practices Committee would be very happy to invite a representative of the local executive council—which he thought was the appropriate local body, rather than the local medical committee—to an interview.

A motion by Derby asking the committee to take steps to ensure that all medical appointments made on behalf of various Ministries be made through the local medical committee or by advertisement was carried.

Dr. D. F. Whitaker (Surrey) moved, and it was agreed, that in the filling of vacancies caused by death or retirement, when the Medical Practices Committee departed from the recommendation of the executive council the committee should inform the executive council of its reasons for so doing. Dr. J. F. Murphy, a member of the Medical Practices Committee, gave an outline of the procedure which the committee adopted.

Dr. R. C. Burton (Sheffield) asked for an amendment of the regulations so that notice of the successor to a practice might be given to the patients a month before the new practitioner took over the list. Dr. A. Beauchamp said that this would mean another month's delay, and there were enough delays already. Dr. Burton explained that what he had in mind was not a death vacancy but a vacancy on retirement, the practitioner giving normally three months' notice, so that the last of these months might be taken for the notice of the successor and there need be no delay. His motion on the subject was, however, lost.

Various Practice Matters

Dr. A. B. Davies (Walsall) asked that the committee be instructed to take up with the Ministry at an early date the burden of work falling upon practitioners. Owing to the wide range of the Act, there were more matters on which people consulted the doctor and more benefits which they could receive. This resulted in longer surgeries and an increased number of visits.

Dr. Wand said that the committee was by no means unmindful of the additional burden, but its immediate task was to rectify the pool. The volume of work had no relationship to the total amount of money in the pool, but it had a relationship to the permissible maximum list, and this might in turn affect the way in which the pool was dealt with. He hoped the Conference would leave it to the committee to use its common sense to make the right decision at the right time. On this understanding he accepted the instruction.

Dr. Wand said that the position with regard to fees for vaccination and immunization remained most unsatisfactory. It had been hoped to have a further conference with the Ministry during September, but nothing had happened. A motion of protest at the delay was carried, and the Conference endorsed the action of the committee in informing the Ministry that it would take no steps to discourage the refusal of the return of reports of vaccination and immunization pending the satisfactory conclusion of negotiations.

Dr. Kennedy (Isle of Wight) protested that the proposed mileage payment in respect of maternity services was inadequate, and that payment should come from the same source as payments for maternity services. Dr. Wand pointed out that when the Ministry's offer of an extra half million for the mileage fund was accepted it was understood that the maternity mileage payment would come out of it. He begged that the matter be left for at least a year to see how it worked, and it could then be seen whether modification was needed.

After a short discussion the Isle of Wight motion was lost, and the same fate attended a motion by Buckinghamshire calling for a reinvestigation of the method of payment.

Medical Services Committee Procedure

Dr. A. G. Holman (Norfolk) asked the Conference to express the view that an independent chairman with legal qualifications should be appointed to preside at Medical Services Committee inquiries. The chairman was elected by the lay members of executive councils and sometimes looked upon himself as prosecuting counsel. Dr. C. M. Stevenson (Cambridge) said that, from his experience of Medical Services Subcommittees in the old days, they often had a more sympathetic hearing with a non-legal chairman than with a legal chairman whose mind was bound up with the technicalities of the law. Dr. F. Gray (London) said that if the motion were carried they might very well get rid of a fair-minded non-legal chairman and have one with legal qualifications but with bias. He begged them not to pass any hasty or dangerous resolution.

The Norfolk motion was lost.

Dr. Kennedy (Isle of Wight) proposed that the Minister be pressed to provide machinery for complaints against patients, as under the old N.H.I. regulations. Dr. J. C. Arthur (Gateshead) supported this, pointing out that a large number of patients coming under their care were in no way familiar with the old insurance or club rules.

Dr. Wand said that the mild way in which the Isle of Wight and Gateshead had put the case for rules of conduct for patients with appropriate disciplinary machinery compared unfavourably with the forcefulness with which his committee had itself presented this question to the Ministry. It was intolerable that the action of some small number of their patients should pass completely unchallenged.

The Isle of Wight motion was carried.

General Practitioners and Hospital Work

Dr. Talbot Rogers (Kent and Canterbury) proposed:

That this Conference, having given attention to the circular letter "Changes in the Use of Hospitals: General Practitioner Hospitals" (published in the *Supplement*, October 15, p. 168), considers that the advice given therein by the Minister of Health to regional hospital boards with regard to proposals for the change of function of cottage hospitals, the continued provision of beds which shall be in the charge of general practitioners (including maternity beds in the charge of general-practitioner obstetricians), and the suggested establishment in district general hospitals of posts as clinical assistants available to general practitioners, is sound and acceptable. The Conference suggests to local medical committees that they shall take every opportunity to press in their areas for action to be taken by regional hospital boards and hospital management committees in accordance with the advice given in this circular letter.

He considered that the circular letter was one of the most important documents issuing from the Ministry during the last few years. Most of the regional boards had been working steadily during the last eighteen months on rearrangements.

and were now in the process of deciding on the future function of the hospitals. During the course of this examination of the work of their hospitals they had in many cases brought forward plans for changing the function, and often this had meant in practice the displacement of the general practitioner from the hospital. This related particularly to cottage hospitals and small hospitals undertaking maternity work. It was therefore with pleasure that they found this circular letter going out to regional boards. This was almost a charter for the general practitioner. The Ministry was urging here the necessity of maintaining a type of hospital they all hoped to see in which the general practitioner had charge of beds. He suggested that local medical committees should use this in their approach to hospital management committees.

Dr. F. Gray, seconded by Dr. H. H. D. Sutherland, moved to omit the words "and the suggested establishment in district general hospitals of posts as clinical assistants available to general practitioners." Dr. Gray considered that these were dangerous words in view of the relative status of general practitioner and consultant. Any consultant by the age of 40 could earn more than any general practitioner who had managed to get a full list. If they accepted the relation of general practitioner to consultant as that of clinical assistant it might have unfortunate implications on respective remuneration.

Dr. Talbot Rogers accepted the amendment, not because he thought the position was quite as dangerous as Dr. Gray suggested, but in order to get unanimous agreement.

Dr. D. F. Hutchinson (Middlesex) mentioned the different attitude of regional boards towards the general practitioner position as a result of the circular. Dr. W. D. Steel (Worcester) referred to the phrase in the circular "treatment within the scope of a general practitioner." This was satisfactory as far as it went, but it did not take into account the general practitioner who in the past had been in the habit of performing certain specialist operations in the hospital continuing that type of work. He hoped they would be able to establish the position of the general-practitioner specialist. It appeared also that it was not anticipated that in maternity departments there should be a general practitioner wing. If in a general hospital there was a general practitioner wing, there should be a similar provision in maternity departments.

Dr. N. G. Thomson (Hertfordshire) said that in his area they had lost their general practitioner hospital, and in its place they had been offered 12 beds in a hospital in which they were given no other facilities such as a theatre, and they had also been offered six clinical assistantships in a big hospital, but these six were all of a different nature, so that a general practitioner working in one clinical assistantship would have no chance of meeting consultants in other branches. The board would be likely to expect the clinical assistantship to have priority over the claims of general practice.

Dr. Talbot Rogers's resolution, with the deletion of the words which Dr. Gray had proposed should be left out, was carried unanimously.

A resolution by Cambridgeshire protesting against the exclusion of general practitioners from the clinical assistant type of post was carried. The mover explained that he had principally in mind teaching hospitals. A further motion by Hastings protested against the regulations whereby a practitioner not in contract with a regional hospital board was not allowed to attend his private patients in the private wards of a hospital, and this also after some slight discussion was carried.

A motion by the Isle of Wight deprecating the exclusion of large numbers of general-practitioner specialists from hospital work was carried. On a further motion Dr. Howie Wood asked the Conference to express the opinion that £25 per occupied bed was totally inadequate as remuneration for general practitioners on staffs of cottage hospitals, unless such items as anaesthetics and assistance at operations carried additional payment. Dr. K. J. T. Wilson (Dorset) also complained of the inadequacy of the payment.

Dr. Wand hoped this would be referred to the committee without too much expression of opinion at the moment because the anaesthetics position was still in process of being cleared up.

The motion was referred to the committee.

Assistants

Dr. D. C. Wilson (Inverness) was anxious that the Medical Practices Committee should not agree to the application of an assistant to begin practice as a principal in his own right in the same area as his principal without the latter's consent. Dr. I. D. Grant said that the ethical position was not within the sphere of the Medical Practices Committee. The obvious protection for the principal was to ask the assistant to sign a bond.

Grants for training assistants led to a sharp discussion. Dr. A. Winstanley (Lancashire) moved:

That this Conference is opposed to the payment of grants for trainee assistants.

Of the many unsatisfactory features of the Service his committee believed this to be one of the most undesirable. It subsidized a successful practitioner at the expense of his colleagues. It set practitioner against practitioner. It was said to implement a recommendation of the Spens Committee, but in fact it did not give effect to the Spens recommendation. Dr. P. A. T. Lowden (Hampshire) supported this contention.

Dr. Wand hoped the Conference would not come to a decision at the moment. The committee intended to look at the problem again when the scheme had been in operation for about a year.

Dr. Winstanley was willing to have it referred to the committee on the understanding that it was reconsidered at the end of a year.

Dr. A. N. Matthias (Middlesex) said that his committee considered it should be obligatory for a formal contract to be entered into between the trainee assistant and the doctor undertaking the training. As a medical assessor to a tribunal his experience was that doctors were bad business men, entering into all sorts of obligations without any proper form of contract.

Dr. Wand asked if this meant that even if the principal did not wish to enter into a contract he must do so. Did it mean that the form of contract should be legally watertight? The model form of contract put before them was overthrown in the courts of law.

A motion to make it obligatory for a formal contract was negatived.

Health Centres

Dr. Wand moved approval of the action of the committee in not opposing the clause in the amending Bill which would make it possible for general practitioners associated with a health centre to attend private patients at the centre. The clause was permissive. It would still be possible for practitioners in an area to make representations against the carrying out of private practice in a particular health centre if they so desired.

The motion was carried, and Dr. Wand then proceeded to move:

That it be regarded as an essential preliminary during the experimental period that, in every area in which a health centre is to be opened, no doctor (other than one of the principals in the health centre, or a doctor who, at the commencement of a specified period, had premises in the area from which he practised and was at that time on the executive council list) should be allowed to open a surgery (including a surgery at his residence) within an agreed area around the health centre, for a specified period before and after the opening of such centre.

The Health Centre Subcommittee had been considering the protection of a doctor who wished to go into a health centre. He had in mind the case of a doctor practising midway between two health centres a mile and a half apart. On deciding to go into one of them, he might find himself cut off from half his practice, which was inevitable, but in addition he would know that anybody, if it was an open area, could come in and take consulting-rooms next door to his own previous rooms. If the health centre experiment was to be carried out as they all desired, it was essential that the best doctors should not be discouraged from going into the health centre. Therefore he hoped that this proposal, if the Conference approved, might be included in the amending Bill.

The motion was carried unanimously.

Maternity Medical Services

Dr. J. C. Arthur (Gateshead) moved that, where maternity hospitals do not fully implement their responsibilities to their booked patients during pregnancy, the general practitioner who was called upon to undertake such responsibilities should be entitled to some portion of the maternity fee. This motion was agreed to.

Dr. W. H. Hayes (Bristol) moved a long resolution deploring the tone of members of the Royal College of Obstetricians and Gynaecologists in their ill-considered criticism of general practitioners, and instructing the General Medical Services Committee to seek the help of the Central Consultants and Specialists Committee in considering means of preventing the publication of such criticisms without the members attacked being given the opportunity of stating their case. The resolution went on to call for consideration whether there was any justification for such statements: if the statements proved to be mainly true, then immediate means should be found for correcting weaknesses in the teaching system, and if mainly untrue then the fact should be published, including an apology from the Royal College responsible.

The resolution was carried unanimously without discussion.

Autonomy of the Committee

Dr. Hayes further moved that, in view of statements that the General Medical Services Committee was a B.M.A. Committee, the Conference should emphasize that it was a committee responsible to the Conference only and in no way responsible to the Representative Body. At the same time he felt sure that the Conference would do its utmost to support the B.M.A.

Dr. Frank Gray reminded the Conference that it had been stated that a gentleman never claimed to be one, but simply took it for granted. The committee, like the Insurance Acts Committee before it, had not claimed to be an autonomous body; it had assumed it, and the arrangement, without too much probing amongst constitutional definitions, had worked well. If such a motion as this were carried it might lead to similar claims on behalf of other sections of the profession and have a divisive effect. They had increased strength in going to the Minister by standing all together.

Dr. W. Woolley said that autonomy had been thrust upon them by the Association. They were recognized at Harrogate as an autonomous body. This motion was merely a public statement that the committee was responsible to the Conference.

Dr. Wand said that the committee was the executive of the Conference, and as such completely autonomous, and yet it had an association with the B.M.A., which was greatly to its advantage. He hoped the meeting would not find it necessary to attempt to define something which was indefinable, but which worked admirably.

It was agreed to proceed to the next business.

Change of Doctor

Dr. O. Williams (Carmarthenshire) moved to recommend to the Ministry that the practice under the old N.H.I. should be reverted to, whereby, except in the case of consent by the two doctors concerned, a patient might change his doctor only at the end of a quarter, and then only after due notice.

The chairman (Dr. Jope) said that during the negotiations it was obvious that the Ministry desired the freest possible change of doctor in order that State practice might resemble private practice, where the patient could change his doctor immediately.

The Carmarthenshire motion was carried by 62 to 47.

Dr. H. Vickers (Middlesex) moved a resolution strongly deprecating the practice of admitting practitioners from an adjoining area to an executive council's list irrespective of the distance from the applicant's surgery to the area of practice, and instructing the committee to discuss the matter with the Medical Practices Committee so that a reasonable limit of distance might be set. He gave instances occurring in Middlesex of practitioners who had come on to the list when their surgeries were many miles away in adjoining counties.

Dr. Grant pointed out that it was of very little use to discuss the matter with the Medical Practices Committee; it was a matter for the Ministry.

Dr. Wand said that as he understood it the executive council had the power to refuse doctors the right to practise in an area where they could not give a satisfactory service. He suggested that the General Medical Services Committee should go through these cases and consider what action, if any, should be taken.

This course was agreed to.

The Shilling Levy on Prescriptions

The last matter to come before the Conference was the announcement made by the Prime Minister three days previously of the shilling levy on prescriptions. Dr. J. A. Pridham moved:

That this Conference place on record its opinion that under no circumstances whatever shall the dispensing doctor be required to be an agent to collect a Government charge on prescriptions.

Dr. J. C. Pearce (chairman, Rural Practitioners Subcommittee), in seconding, further pointed out that when the National Health Service was started there was a definite promise that no financial barrier should be placed between doctor and patient, but here a financial barrier was interposed. He also thought the scheme would be impracticable in rural areas.

Dr. H. H. D. Sutherland proposed and Dr. Frank Gray seconded an amendment to omit the word "dispensing," and this was agreed to.

The secretary read a notice which was being sent out to the Press indicating generally the reaction of the profession, and this received the general assent of the Conference.

Dr. Talbot Rogers (Kent) suggested that in addition to old-age pensioners there were other groups of patients who might well be relieved of this impost. He had in mind poor patients who needed medical care over a long period. The effect of illness on the family budget became increasingly heavy as the illness dragged on.

The resolution, with the word "dispensing" omitted, was carried unanimously.

Other Motions

During the day various motions were carried or referred to the committee without discussion. On the motion of Gateshead the committee was instructed to continue to press for a payment from the Dental Estimates Board to practitioners called upon to deal with dental haemorrhage.

Dr. H. W. Bowyer (Bolton) moved to refer back the paragraph of the Annual Report dealing with treatment of H.M. Forces on leave. His committee thought they should be accepted as temporary residents. The General Medical Services Committee's view was that there should be no change in the existing arrangements. The Bolton motion was lost.

Dr. Kennedy (Isle of Wight) asked that immediate steps should be taken to ensure that the names of Service patients were restored to the list of their previous doctor on demobilization, as was done prior to July 5, 1948. This was agreed to.

Dr. D. L. S. Johnson (Halifax) had a motion expressing strong disapproval of any certificate of incapacity given by an unregistered practitioner being considered by the Ministry of National Insurance, and urged the committee to bring this to the notice of the Minister. He said that in August last an osteopath applied to the local executive council to be put on the list for the purpose of certifying people who were under his care as incapacitated and therefore entitled to draw benefit under the National Insurance scheme. The clerk of the council wrote to the Ministry asking for guidance, and was told that unregistered practitioners could not be included in the Service without amending the Act, but the reply went on to say that certificates of incapacity given by unregistered practitioners were considered by the Ministry of National Insurance "on their merits." This seemed to raise a fundamental issue which the committee should take up. The Halifax motion was carried.

On the question of the Special Inducement Fund Dr. Wand said that the Ministry of Health had been approached in order to secure a widening of the scope of the Fund so as to include

definite cases of hardship irrespective of the type of area in which the doctor was practising. He read a statement from the Ministry which in his view represented a very marked improvement in dealing with hardship cases.

The Inverness Committee called for the setting up of a commission to go into the nomenclature of drugs and the standardization of bulk in packages with a view to eliminating waste and extravagant prescribing. The mover pointed out that there were a great many varieties of aspirin under different trade names. The proposed commission should consist of doctors, pharmacists, and manufacturing chemists. Dr. Wand accepted the reference of this motion to his committee, but said that it might prove to be a matter for the Science Committee of the B.M.A.

A motion by the Isle of Wight expressing the view that practitioners should have free choice of venue for refresher courses was referred to the committee

A report of the trustees of the National Insurance Defence Trust was received and approved. It was stated that an appeal for the continuation of contributions to the new Trust would be sent out to local medical committees within a week or two.

Chairman Re-elected

Dr. Jope was unanimously re-elected chairman of the Conference, and the six retiring members of the General Medical Services Committee were re-elected—namely, Drs. A. Beauchamp, S. A. Forbes, I. G. Innes, J. A. Ireland, J. A. Pridham, and F. M. Rose.

Dr. R. W McConnel (Buckinghamshire) moved:

That the Conference wishes to express during the first year of work of the Service its confidence in the General Medical Services Committee, and its extreme satisfaction with the work done by the committee.

This was carried unanimously and with acclamation.

A vote of thanks to the chairman closed the proceedings.

CONFERENCE DINNER

At the close of the Conference the representatives entertained the members of the General Medical Services Committee at dinner at the Dorchester Hotel under the chairmanship of Dr. Walter Jope. Dr. S. Noy Scott, in proposing the committee's health, suitably expressed the thanks of the Conference and of general practitioners all over the country for their ungrudging and self-sacrificing labours. Dr. Wand, chairman of the committee, said that he felt very humble when he recalled the chairmen of the old Insurance Acts Committee—Brackenbury, with his incisive mind and kindly heart; Dain, a leader of great courage and one who evoked much affection, and Gregg, of whom more would be said later in the evening. The new committee had a great tradition to maintain, but it was a most knowledgeable body of men (with one woman), and very hard-working and conscientious. He referred especially to the Scottish contingent. From them had arisen one of the ablest medical politicians they had had in recent years in the person of the chairman of the Conference, who had been a great help in their deliberations. They thanked also his wife, Dr. Christina Jope, without whose aid in his Lanarkshire practice he would never have been able to accomplish his work at Headquarters. Dr. Jope's health was then proposed by a fellow Scot, Dr. A. C. Hendry, of Aberdeen.

The presentation of a handsome grandfather clock was made to Dr. E. A. Gregg by those who had served under him during his chairmanship of the Insurance Acts Committee. In making the presentation Dr. Wand said that they rejoiced that after his long service in the chair of the committee he was now carrying his wisdom and understanding into the wider sphere of the chairmanship of Council. Dr. Gregg said that the chimes of the clock would remind him of many friends, some of them gone, and many happy and laborious days. The I.A.C. was "the best committee of the British Medical Association," and now it had handed on its traditions to a successor with the same spirit and much the same membership. The Conference had shown that some people were bothered about the word "autonomous" and the relation of the committee to the B.M.A. One of the finest pieces of work ever done in the B.M.A. was the creation, on the introduction of the National Health Insurance Act, of a special organization for the discharge of this part of its task. "Don't have any doubt about your relationship. You are part and parcel of one of the finest organizations in the world. The Association is not a building nor even a staff, it is a united body of medical men and women expressing itself to the Government and to the public at large."

The Dain Fund

After the usual compliments to the staff, medical and lay, which were responded to by Dr. Hill and also by Dr. D. P. Stevenson, secretary of the committee, the last word of the evening was with Dr. Dain, who spoke about the Dain Fund, established a few years ago for the assistance of the sons and daughters of medical men whose fathers, owing to early death or other misfortune, had been unable to complete their children's education. The fund had had some useful additions, notably a handsome donation of £150 from the Metropolitan Counties Branch. The trustees had decided that half the money coming in each year should be invested to increase the capital and half should be spent on the assistance of needy cases. Responsibilities had been undertaken which ran into nearly £1,000 a year. He hoped that local medical committees would follow the example of the old panel committees in making generous donations to this fund.

The chairman endorsed the appeal, and a collection was taken at the tables, resulting in a sum of £122.

THE DAIN FUND

REPORT OF THE TRUSTEES, 1948–9

This report covers the year ended August 31, 1949, a period during which many requests for advice and assistance have been received, considered, and whenever possible dealt with either by the Fund or by obtaining assistance from other bodies.

It will be remembered that last year an unusually large number of new cases (nine) were accepted by the Trustees. It was appreciated that many of these would require continued assistance, but under the present policy of the Trustees it has been agreed that to accept a long-term responsibility for the education of a child is the wisest way of using available funds rather than giving a large number of smaller sums, which, though providing temporary relief, would inevitably mean further help and probably transference to other funds or associations for final assistance.

Nevertheless it has been possible to take on two new applications, involving help to three children, details of which are given.

Case 1.—The widow of a general practitioner made application for assistance towards the fees of her youngest son while at the College of Estate Management. The applicant's three other children live at home and are able to contribute to the maintenance of the house, but there were no available funds for fees and maintenance of this boy. The training is for a period of three years and the Trustees agreed to allow £50 per annum subject to satisfactory reports on progress.

Case 2.—The widow of a practitioner whose death occurred in 1947 has struggled to support her family of three children by running a small shop. Her two elder children, a girl aged 20 and a boy aged 18, have both started their medical training; the third child aged 15 is at school. Application was made for financial help for all three children. The help required for the youngest child was promptly and most generously given by the Royal Medical Benevolent Fund, and the Trustees of the Dain Fund, having received good reports on both medical students, decided to assist by a grant of £75 per annum for each, making a total of £150 per annum.

This is an example of the type of case which the Trustees feel particularly they should assist, and, subject to satisfactory reports from the dean of the medical school, the Trustees plan to continue this grant to enable these two promising students to complete their training for a medical career.

It was with great regret that the Trustees, owing to lack of funds early in the financial year, had to refuse financial

help to three other children who were particularly suitable. Arrangements were made, however, for help to be forthcoming from other sources.

Of the thirteen remaining cases which have been helped this year, in three the periods of education for which the Trustees undertook responsibility have now been completed. The first, a boy doing his dental course, has had consistently good reports and is taking the last part of the final examination in the autumn. The second, a girl, has done well at school, gaining the School Certificate with six credits, and has now been accepted for training as a physiotherapist. The third case is that of a boy who is sitting for a classical scholarship at Oxford. It is a matter of great satisfaction to the Trustees that these children have been successful and have fully justified the hopes of all interested in them and their future.

In the other ten cases grants have varied in amount from £30 to £105 per annum. In five cases additional assistance has been given by local medical committees, a fact which is greatly appreciated both by the Trustees and by the recipient of the grant.

All inquiries are dealt with as expeditiously as possible and advice is given by the secretary on many matters other than actual finance. The Trustees would like to express their thanks to the Royal Medical Benevolent Fund and the Royal Medical Foundation of Epsom College for their co-operation, help, and advice in many cases. By sharing responsibility with other bodies it is often possible to assist a large number of cases for longer periods of time.

It will be evident that if the work of the Dain Fund is to continue more money is required. As has been stressed in previous reports, the annual income of the Fund is small, though the capital is slowly being built up under the Trustees' policy of investing one-half of all moneys received. Income from investments was under £150, but owing to the generosity of donors a sum of £1,641 was received, which made it possible to distribute £960 during the year.

The Trustees, in appealing to the profession for monetary pport, wish to suggest that all doctors who are interested in and desire to help the Dain Fund should complete a form of covenant for a seven-year period. Such a covenant in the hands of the Trustees means that the Trustees will be in a position to know that a definite income is assured, and indeed by giving a donation in this manner the actual sum available to the Trust is considerably increased. In the same way it is hoped that local medical committees, who have been most generous in the past, will consider the possibility of this form of donation.

The Trustees wish to express warm appreciation to the council of the Metropolitan Counties Branch of the British Medical Association for the most generous gift of £150 from the proceeds of the Charities Ball held in May. It should also be reported that £1,000 paid by the *Daily Mirror* to the British Medical Association was given by the Council to the Dain Fund.

In presenting this report the Trustees feel that every effort has been made to use available funds to the greatest advantage to individual cases. In order to help these children of professional colleagues, the Trustees appeal most sincerely for the generous support of all doctors.

All donations and inquiries should be addressed to the secretary to the Trustees of the Dain Fund at B.M.A. House.

H. GUY DAIN,
Chairman of the Trustees.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar.

Non-County Borough Councils.—Dartford, Wallsend.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huyton-with-Roby, Redditch (restricted to new appointments), Tyldesley.

Correspondence

Representation of Consultants

SIR,—I have read with some disquiet the letter from the members of the South-West Metropolitan Regional Committee (*Supplement*, October 22, p. 185) and regret that they have come to the unfortunate decision "that if the Central Committee of Consultants and Specialists continues to be subordinated to a Joint Committee it will consider withdrawing its representatives from the Central Committee and relying on representation of its members by other means."

This presents an entirely misleading picture. The Central Consultants Committee is no more subordinate to the Joint Committee than are the Royal Colleges. Each constituent body has the right to present its case to the Ministry direct, if there be any disagreement amongst them.

During the year that the Joint Committee has been working there has not been the slightest suggestion of any such action being contemplated. Indeed, such has been the unanimity of the Joint Committee that it has been able to obtain many concessions from the Ministry towards improving the terms and conditions of service.

It is begging the question to say that it acted without authority in agreeing with the Ministry to recommend the terms for the permanent contracts for hospital staffs. The facts are these: The Central Committee recommended to the Joint Committee that certain changes should be made before such action could be taken. It was with this reference that the representatives of the Central Consultants and Specialists Committee, with representatives of the other constituent bodies, met the Ministry. The Ministry gave certain assurances, details of which were published in full in the *Supplement* of July 23 (p. 53). After considering those assurances, the Joint Committee announced on July 22 that it was "now able to advise hospital staffs to enter into permanent contracts." The Joint Committee also decided, with the assent of the Ministry, to continue negotiations on a number of outstanding points. These decisions of the Joint Committee were endorsed by the Central Consultants and Specialists Committee.

At the last meeting of the Central Consultants Committee we had before us a letter from the Ministry asking which body they should consult with reference to the medical membership of the Whitley Council. It is desirable that these Councils should be set up at an early date, and, as the Joint Committee had established its position with the Ministry as the one body representing the consultants, it seemed that the Joint Committee was the right and proper body to be consulted by the Ministry for this purpose.

This decision, of course, must be communicated to the other constituent bodies of the Joint Committee before further action can be taken.

In my view the work of the Joint Committee has fully justified its existence, and it has established good relations with the Ministry and can now go to it with great authority.

If the South-West Regional Committee persists in its demand it will mean that instead of one body representing the consultants there will be several having little authority, which I consider would be an impossible and dangerous situation.—I am, etc.,

Manchester. R. L. NEWELL,
Chairman, Central Consultants and Specialists Committee.

Status of General Practice

SIR,—Whilst agreeing heartily with both Dr. Grant (*Supplement*, October 1, p. 155) and Dr. Duff (October 22, p. 184) that the status of general practice is a fundamental matter, I cannot feel that either of them has dealt adequately with the subject or fairly with their colleagues. The first question in status is, What do you think of yourself? (If you do not think much of yourself it is unlikely that anyone else will think much of you.) Now, both Dr. Grant and Dr. Duff, with their constant

references to trivial complaints and certificates, are implying that good work cannot be done under the N.H.S. Indeed, Dr. Grant—quite naturally in view of his present position—can only think of a good general practitioner in terms of private practice, and Dr. Duff is not quite sure whether he is a rubber-stamp or a finger-post.

Now where does the fallacy lie? For fallacy there surely is. Is it not in this same "trivial complaint" and the G.P.'s attitude towards it? Does not the word "trivial" imply that it is beneath the doctor's notice? Yet do not these trivial complaints include on the one hand all the beginnings of serious illness, and on the other just those cases which can be most easily and quickly cured—by anyone who knows how?

It is usually implied that trivial cases are uninteresting. Well, Sir, interesting work is work in which we take an interest—just that, no more and no less. It is also implied that they are not so difficult to diagnose as advanced cases. Which is easier to see—a large object or a small one? Which is easier to discern—a large deviation from the normal or a small one?

Is not the real reason for all this disgruntlement quite different? As medical students we were all trained by consultants who, however, eminent in their own sphere, showed neither willingness nor aptitude to treat minor ailments. What they did not possess they could not impart, and the G.P. has been left to pick up this knowledge for himself or go without it. We may suspect that those who are always trying to get back into hospital in some form or other (incidentally a regressive attitude) want to get away from general practice not because it is too easy but because it is too hard for them.

Fortunately these are only a small minority. There are many in general practice to-day who have built up large lists, not by either of the methods mentioned by Dr. Grant, but by concentrating on the real needs of their patients, even when these are masked by "trivial" complaints; sorting out those who merely need a word of reassurance, those who need a talk about their domestic troubles, and those whose symptoms suggest the beginning of some serious physical illness and require a careful overhaul. In this way they not only retain the confidence of their patients but also run their practices in an efficient and self-sparing manner. It is inexcusable in Dr. Grant that he should have failed to mention this method, as he is personally acquainted with many of those who practise it.

I am aware, of course, although I am no longer in general practice myself, that the greatly increased resort to the doctor makes things more difficult for all general practitioners, but I still find, from talking to my colleagues, that the efficient practitioners who use this last method find their lives much less burdensome than their neighbours who do not. Perhaps one day we shall realize that general practice has its art and science worth cultivating for their own sake alone.—I am, etc.,

East Hoathly, Sussex. F. GRAY.

Bureau for Assistants

SIR,—The matter of "principal and assistant" has recently become an interesting topic in the *Journal*. This subject has now become very important, as throughout the country assistants are being installed some with and some without hope.

The recent "groans" of the assistant and now the "moan" of the principal (*Supplement*, October 8, p. 163) have prompted me to voice my opinions and suggestions. Both sides have legitimate grumbles, and yet both sides are at fault. The assistant of to-day expects a share in a practice, sometimes in a short space of time, without having earned the right. Does he realize how serious a step a partnership can be? A partnership in medicine is almost a marriage—it is practically made for life—and a "divorce" becomes so complicated financially that the lawyers eventually end up most successfully. Hence the hesitancy of the principals.

When the right man comes along and the practice benefits from his work and knowledge, the principal would be a fool to let him go. Surely six months or one year is not a fair test. There should be a period of two years at least.

Now, what about the right type of assistant? Here I would like to make a suggestion. It is high time that a bureau was set up to protect him or her. This office should be sponsored by the B.M.A. It should have the names of the principals and assistants. All assistants should seek posts through this one and only bureau; references should be exchanged through it; terms of service should be set up in contract form and witnessed. Principals failing to comply with their undertakings should be black-listed, and assistants found to be failing should be black-listed too. Hence we can at least safeguard both sides. Unless this method is adopted, mistrust, fear, and anxiety will always exist.

I look to the B.M.A. to take this step now and sponsor such a scheme. It will give the assistant a fair chance and avoid exploitation; it will give the principal the right assistant. It will also promote trust and restore faith in the profession, which is now sadly lacking, and in this way we will become a happy unit and the standard of medicine will improve. The young assistant will have a future, the principal will find his work shared, and both will profit from each other's knowledge and experience.—I am, etc.,

London, N.13. V. M. SEIFERT.

*** Anticipating these problems, the Association established the Medical Practices Advisory Bureau at the end of 1948. The Bureau is under the personal direction of a member of the Association's Medical Secretariat and has an experienced staff. It has had considerable success in the work suggested by our correspondent.—ED., *B.M.J.*

Private Practice for M.Os.H.

SIR,—It is remarkable how persistent in their silence regarding the progress made—if any—are those responsible for the talks which are supposed to have started on the matter of increasing our salaries. Several months elapsed since the ban on advertisements of vacancies from local authorities in the professional press was imposed as one of the useful forms of pressure to force the issue; again, some three months have passed since that ban has been lifted as the result of a given undertaking that talks will presently start. But nothing of any significance has been reported so far.

This delay—the matter has been lagging behind ever since the appointed day of July 5, 1948—is perhaps due to the heavy burden which lies on the shoulders of the representatives of the "bigger brother" within the profession—namely, the general practitioner, who has just recently been fulfilling the great task of presenting an appropriate demand for additional capitation funds to the amount of £16½ million. It should be borne in mind that there is a marked discrepancy between the length of time which is necessary to bring about a satisfactory solution of the problem and the actual *materia ad disputandum*: for even the conclusion of the peace treaty at Versailles after the first world war was accomplished within three months, and the amputation of our sterling was performed in the record time of a very few days.

It is at this juncture that the most useful recent work of Dr. K. V. Deakin comes in. Indeed, for the benefit of both the general practitioner and his "little brother" within the profession, Dr. K. V. Deakin would be well advised to quote, in his authoritative statistics and analysis of conditions of pay of the medical profession, not the incomes of doctors in Bolton (*Supplement*, October 1, p. 156) and Manchester (*Supplement*, August 27, p. 117) (£1,301 p.a. and £1,280 p.a., respectively), but instead the average salary paid to medical officers of health by local authorities: £750 p.a. That pay compares indeed strikingly with average incomes as quoted from the Bolton and Manchester area, of £2,760 for the dentist, £2,085 earned by the optician, or £1,720 paid to the chemist.

It is not in the interest of the general practitioner and the profession as a whole to witness the disruption of the Public Health Service so far as the work of the medical officer is involved. The exodus of the dental officer from the Public Health Service, which has reached a sub-chronic stage, was and still is certainly advantageous for both—the dental practitioner and the dental officer as well. But our exodus, the exodus of

the "little brother" within the profession, would result in a considerable increase of work, and paper work as well, in the surgeries of the already overworked general practitioner without additional remuneration. Indeed, it must not be forgotten that the bulk of work carried out by the medical officer in the Public Health Service—child-welfare clinics, ante- and post-natal clinics, minor-ailment clinics, etc.—is already financially covered under the National Health Service, and therefore capitated.

It is a pity that we are presenting our demands late in the day so that they unfortunately coincide with the Cripps devaluation wage freeze, which can hardly be regarded as a temporary measure in terms of one or two years, as any Government which may follow on will be pledged rather to decreasing than to increasing expenditure from public funds.

An alternative solution to our problem must therefore be sought and found, and the only alternative proposal, I believe, consists in a change of conditions of service which, if agreed to, will satisfy all concerned parties and evade the inevitable collision with the said Cripps devaluation wage freeze. The prohibition of private practice for the medical officer in public health can no longer be maintained; it belongs to the past and must be lifted. This should be our alternative demand, for it is at present our most precious and only asset. A new appointed day must therefore come into being. The medical officer serving under the local authority within the scope of public health must be free to engage in private practice and subsequently to work under the National Health Service scheme after having completed the duties of his primary employ.

Many ancient nations with a highly efficient public health service have all adopted that system, which has also led to an increase of efficiency of the medical officer, who, while maintaining his original status of medical practitioner, never lost touch with real medicine.—I am, etc.,

Accrington, Lancs. J. KATZ.

Administrative Units

SIR,—I have been very much disturbed to read in the Press the account of the protests made at Shaftesbury by old people who have been forcibly taken from the institution there to Salisbury 20 miles away.

Like all other country doctors, I know a large number of people of the type who made the protest, and I know that nothing short of very severe provocation and deep feeling would have caused them to act as they did. Twenty miles does not seem far in a car, but it is enough to cut these people off from their friends and relatives almost completely, not for a short time as in an acute illness, but for life. Long bus journeys are too exhausting and expensive for old people, and the times are often inconvenient for young ones who are working or have young children to look after.

I should imagine that a number of these patients did not come from Shaftesbury itself, but from the surrounding villages, and the difficulty of the journey would thus be greater.

These Dorset men and women have shown that the spirit of the Tolpuddle martyrs still survives in the South-west, and anyone who believes in the individual as something more than an administrative unit must respect and admire them.—I am, etc.,

Peterborough. MAUREEN PRESTON.

Dispensing and the Chronic Sick

SIR,—Dr. W. A. Hyslop's letter (*Supplement*, October 15, p. 172) prompts me to point out another gross inadequacy in payment to dispensing practitioners—namely, drug requirements of the chronic sick. These would include patients suffering from chronic rheumatism in all its forms, chronic cardiovascular disease, carcinoma of the prostate, as well as the incurables and neurotics. A chronic rheumatic patient alone will easily take 2,000 tab. codeine co. a year at an approximate cost of 30s. per 1,000. Other chronics will require £3–£4 worth of drugs per year in the ordinary course of events, without allowing for extra dispensing for the ordinary common ailments. Six-and-sixpence a year does not go very far towards keeping a chronic rheumatic supplied with drugs, and, as Dr. Hyslop points out, the capitation fee for dispensing patients should be reviewed in the light of experience.

To help prescribing for these "chronics" the executive council will not allow one to remove them from one's dispensing list even though one arranges to keep the patient adequately supplied with medicines. We are politely told that the extra cost of dispensing for the chronic sick is compensated for by the people who require no dispensing during the year. I am certain it could be shown, if one had the time to spend, how utterly ridiculous such reasoning is. But the Ministry's word is final, and one must take a "chronic" on to one's dispensing list knowing full well it will mean a net loss of several pounds a year.

The faulty ruling here is that a dispensing practitioner has only two ways of claiming for his drugs. The easiest is by the inadequate capitation fee, and the other entails a great deal of irritating and unnecessary clerical work. This latter method turns out to be more costly to the Ministry as well as more exacting to the doctor.

My suggestion is for a review of the drug allowance, and for the doctor to have a free choice of the patients for whom he will dispense and not to be domineered by the local executive councils to be told what he must or must not do.—I am, etc.,

Garforth, Yorks. J. F. ROBINSON.

TUBERCULOSIS IN EUROPE DURING AND AFTER THE SECOND WORLD WAR

BY

MARC DANIELS, M.R.C.P., D.P.H.

Member of the Scientific Staff of the Medical Research Council

Among the suggestions made by Dr. Milroy for the lectures on State medicine and public health which he established over 60 years ago is the following :

"XVIII . . . that more diligent and continued attention may be paid than has yet been attempted in this country to the study of the accurate *Geography of Diseases*, (and to) the exact date of each epidemic prevalence . . . of the ordinary endemic maladies in different countries and localities, together with a brief notice of any exceptional feature . . . characteristic of each aggravated manifestation of the malady in question, so that some record of its varying natural history may be preserved for the benefit of future times. The want of thoroughly trustworthy information on this department of professional investigation has had much to do with causing the numerous errors and fluctuations of opinion which have hitherto retarded the real progress of sound knowledge on various questions. An accurate geography of many diseases is often essential to the complete determination of their true natural history."

It is a sobering thought that these words, written in days when the epidemiological study of infectious diseases was still in its infancy, are as true of tuberculosis to-day as they were then. The amount of work that has been done on tuberculosis, and particularly the amount that has been published in the past 50 years, defies calculation ; but the number of sound epidemiological studies of the disease can easily be enumerated, and our knowledge of its natural history is still rudimentary. In fact, though there has been a progressive and striking reduction in tuberculosis mortality since the time of Dr. Milroy, it is still the main killing disease at the most productive ages of man. Dr. Stocks (1944) has estimated on the basis of a combination of morbidity and mortality statistics that in 1938 there must have been at any one time in England and Wales about 100,000 persons with clinically active pulmonary tuberculosis and about 650,000 in a quiescent state ; and of this total about 60,000 were expected to die eventually of the disease. Its effect on the productive capacity of the population is demonstrated by the fact that the mortality from the disease in England and Wales in 1945 represented a loss of 565,000 person-years of future lifetime between the ages of 15 and 65 (Stocks, 1949).

The nineteen-thirties and the early years of the war saw discoveries of so great importance in the treatment of acute infections and in the prevention of such diseases as typhus that they reduced to relatively low proportions the toll usually taken by war in disease. It had become a commonplace to compare the numbers who died in past wars from casualties in battle with those dying from diseases such as typhus, dysentery, and typhoid. But for the second world war this does not apply ; though there were some epidemics of these diseases they did not reach anything like their former gravity and distribution. Tuberculosis rates, however, rose in every European country seriously affected by the war, and there is now a growing realization in Europe that tuberculosis is our main public health problem. A study of the trends of the disease during the war years may be of some value in contemplating future action.

With these considerations information is presented here on wartime and post-war tuberculosis trends, and on the development of tuberculosis services in different European countries since the end of the war. Much of the information was collected during service with Unrra ; the disturbing scenes one saw then aroused and focused interest on some of the problems to be discussed here.

DEATH RATES AND PREVALENCE*

Tuberculosis Mortality

When one presents statistics of tuberculosis in Europe it is with a feeling that they are better than no information at all, but not much better. There are countries in which as many as 50% of the deaths are not medically certified, and where 15 to 20% are registered as being due to unknown causes. Even in France as many as 10% of deaths are registered as of cause unknown. Most regional statistics within the European countries are unreliable ; in most cases the deaths are registered at the place where they occur and are not referred to the residential population. The fear of tuberculosis in backward populations is responsible for much evasion of tuberculosis certification. In addition to all this, one must take into account the many factors operating during war and the German occupation, conditions to make statistics of any kind many times less reliable than before. The drafting of men into military service or into forced labour for the Nazis, the Jews deported, the numbers taken prisoner of war or thrown into concentration camps ; the people who died away from their homeland by violence on the battlefield, in air raids, or in gas chambers, or of untreated diseases in camp or elsewhere ; the migration of millions during and after the liberation, including the return to their homes of prisoners of war many of whom had a high incidence of pulmonary tuberculosis : these factors combine to modify all statistics

*The first of two Milroy Lectures (abridged) delivered at the Royal College of Physicians on February 15 and 17, 1949.

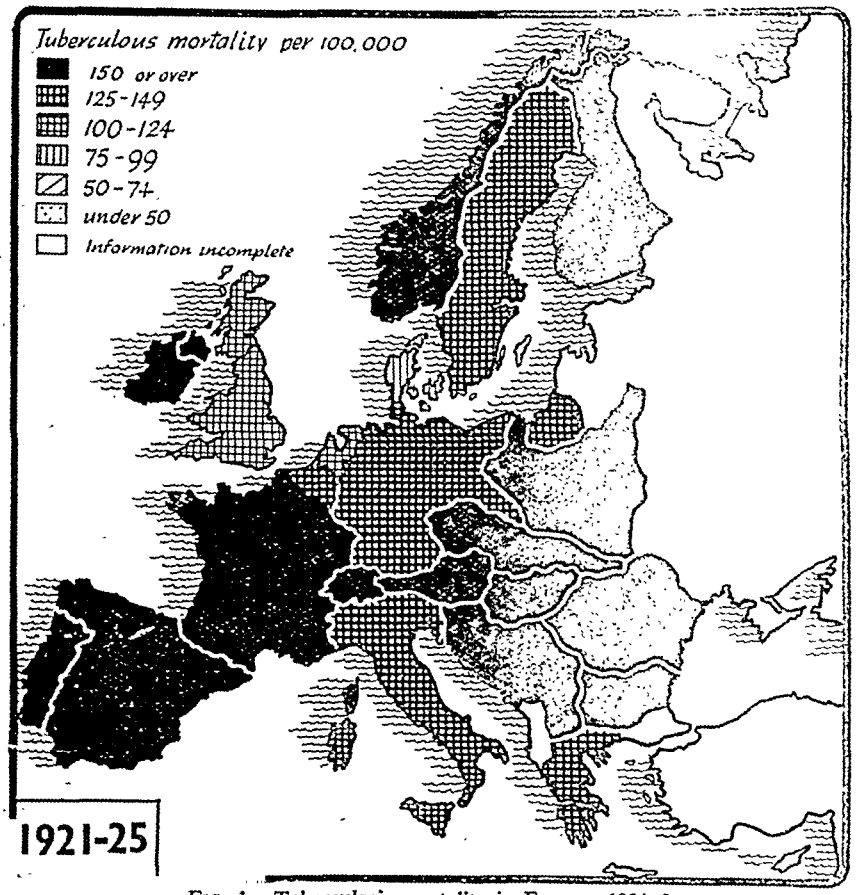

FIG. 1.—Tuberculosis mortality in Europe, 1921–5.

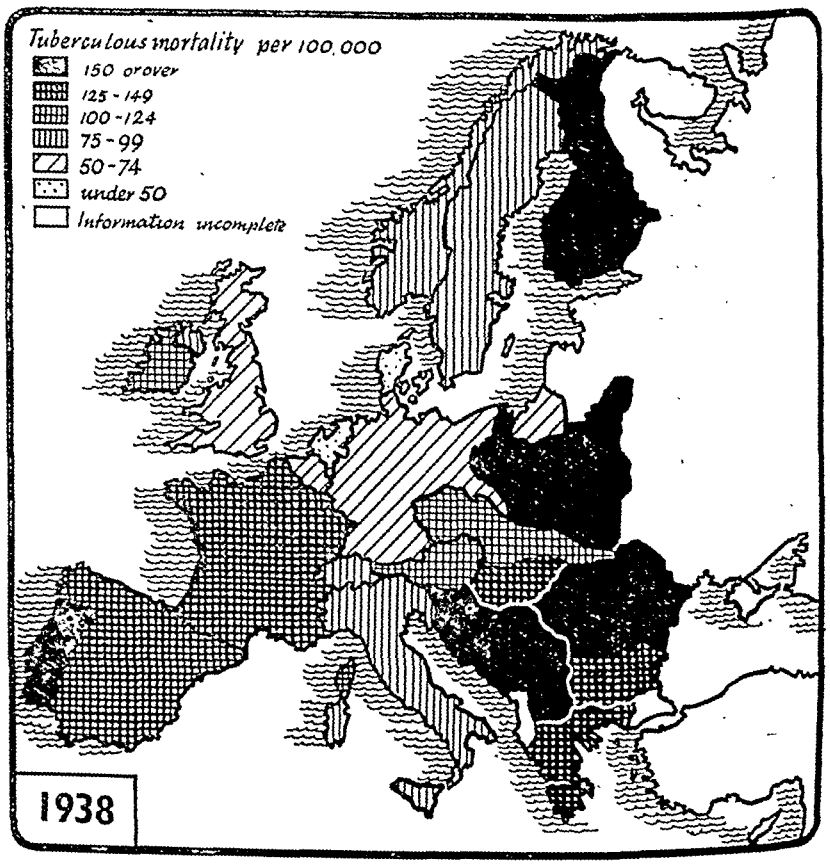
obtained. So all the figures to be given here bear this reservation : they are the statistics that were obtainable in the circumstances, the circumstances of war and post-war.



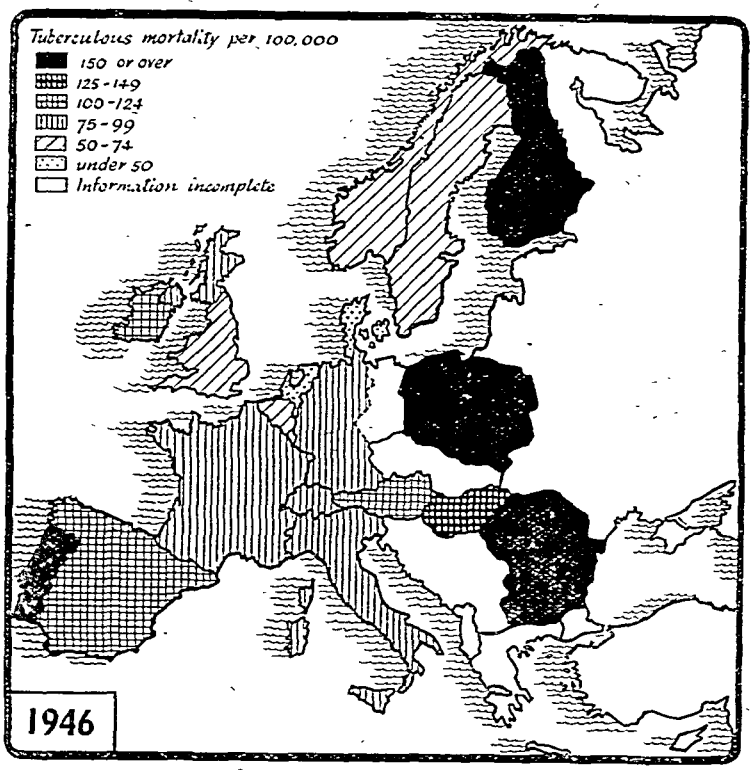
Before looking at the trends of tuberculosis mortality during and after the second world war we can rapidly view the remarkable fall in the rates over the past 50 years. The tuberculosis death rates fell in several European countries from above 200 per 100,000 in 1885 to below 100 in 1935. The most striking fall was in Denmark ; the rate there was one of the highest recorded in Europe in 1885, with a mortality of nearly 300, and in 1935 it was below 50. In most European countries, and particularly in Germany, Austria, and Belgium, there was a sharp rise between 1914 and 1918. A striking feature of the trends is that shortly after the end of that war the rate had declined to a level which it would normally have reached if the pre-war trends had continued uninterrupted.

The changes in the period between the two wars and during the recent war are demonstrated in the maps (Figs. 1–3). In Fig. 1 are charted the tuberculosis mortality rates in the countries of Europe in the period 1921 to 1925. It is obvious from this map that tuberculosis death rates in European countries were in the nineteen-twenties still very high according to present standards in all countries except Denmark ; the mortality was highest in Eastern Europe, France, Spain, Norway, and Ireland.

The second map (Fig. 2) demonstrates the striking change which had taken place by 1938. In England and Wales, Scotland, Belgium, Holland, Denmark, and Germany the tuberculosis mortality had fallen below 75 per 100,000, and in Norway, Sweden, Switzerland, and Italy it was below 100. In France, Spain, Portugal, and practically the whole of Eastern Europe the rates were still very high, though in Czechoslovakia and in Austria there had been some improvement. It is this particular picture that we must bear in mind in considering to what extent the tuberculosis situation was affected in the different countries by the conditions of war.

In Fig. 3 are charted the tuberculosis death rates for 1946. Statistics for some countries are as yet so incomplete that it has been necessary to leave them blank, but an outstanding feature is the relatively low rates in the whole of the mid-continent of Europe : in France and in Norway and Sweden the mortality was lower than in 1938, in Germany and Scotland somewhat higher. We have figures as shown for Poland, Rumania, Hungary, and Bulgaria, and it is justifiable to assume that the tuberculosis mortality in the other Eastern European countries is as high as in these. Before the war the rates in these countries were among the highest in Europe.

FIG. 2.—Tuberculosis mortality in Europe, 1938.



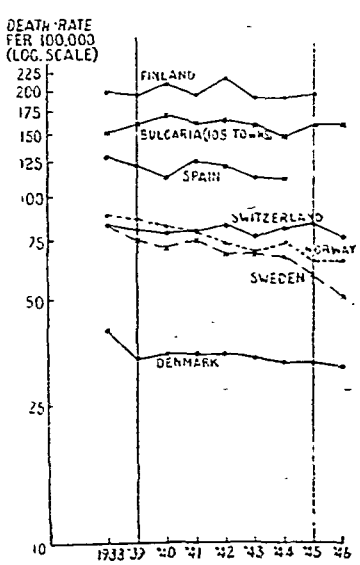


FIG. 3.—Tuberculosis mortality in Europe, 1946.

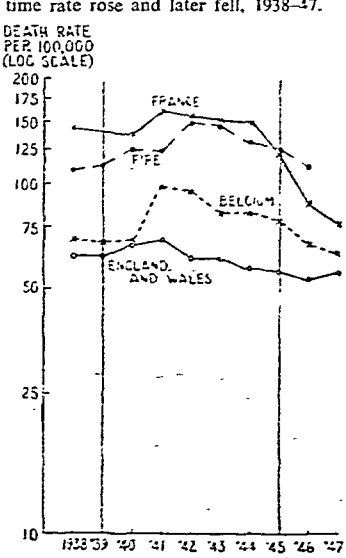
Coming now to a study of what happened in each country during and after the war, we can consider three main groups of countries: one in which there was little or no wartime rise in tuberculosis mortality, a second group in which there was a rise in the early years of the war and then a continuous fall, and a third group in which there was a rise in the latter part of the war.

FIG. 4.—Tuberculosis mortality in European countries having little or no wartime rise, 1938–46.

I. Countries in Which there was Little or No Wartime Rise (Fig. 4)

In Denmark the rate was low in 1939 (rate 34) and slightly lower in 1945 (rate 33). It has the lowest tuberculosis mortality in Europe. At the beginning of the century the rate was as high as in most other countries. In the past 50 years there has been a very notable rise in living standards in this small country, and during the period between the two wars public social care was developed considerably. In this war Denmark fared better than most countries; certain food supplies were limited, but there was never an acute shortage. In a number of other countries with particularly high tuberculosis rates before the war the rates remained high but there was no significant change, and Spain, Bulgaria, and Finland are typical of these. Switzerland had a medium rate, and, though there was an arrest in the decline of the pre-war years, there was no serious rise. Finally, in two countries, Norway and Sweden, there was a definite fall during the war years—in Sweden from 82 in 1938 to 51 in 1946, and in Norway from 88 to 65. There was a rise in 1943 and early 1944 in Oslo, attributed to a deterioration in the food supply.

II. Countries in Which the Rate Rose in the First Years and Fell in the Later Years of the War (Fig. 5)



The principal countries showing this trend are England and Wales, Belgium, Eire, and France.

In Belgium the rate rose from 69 to 98 in 1941 and fell subsequently to a level in 1946 just below that of 1938, and there was a further slight decline in 1947. There is enough in the chaos of the first two years of the war to explain the rise to a peak in 1941: the destruction and occupation of sanatoria, the discharge of patients to their homes, the breakdown of food distribution, the overcrowding and lack of hygiene. However, the central tuberculosis organization was re-established rapidly, after some opposition from the occupying authority, and by 1942 there were almost as many sanatorium beds available as before the war. Double rations were accorded by the dispensaries not only to patients with acute tuberculosis but also to those whose lesions had been active within the past five years. All things considered, there is enough to explain the rapid recovery after 1941, though it is important to note that the pre-war level had only just been reached in 1947.

In Eire there was a continuing rise until 1942–3; apparently Eire was the only neutral country in Europe to suffer from wartime conditions to this extent.

The death rates for France show an interesting phenomenon. The curve for the whole of France shows a rise in 1941 and a subsequent decline, at first gradual and then quite steep. The rate now is little more than half that for 1938. These trends were not the same throughout France. The curve for Paris shows the

FIG. 5.—Tuberculosis mortality in European countries in which the wartime rate rose and later fell, 1938–47.

general trend in an exaggerated form, with an acute rise from 155 in 1938 to 215 in 1941 and subsequently a very rapid fall to a level far below that of 1938 (72 in 1947). But other regions showed quite different tendencies. In Normandy, Brittany, and Eastern France there was an ample supply of animal food and milk, and in these regions, where there had always been a high mortality from tuberculosis, the rate declined throughout the war. In the South, on the contrary, in Bouches du Rhône, in Vaucluse, and in Var, the tuberculosis problem continued to be acute up to 1943, and this can be related to the very severe food shortages in these districts.

For France one must make reservations on the absolute value of mortality figures, but comparisons between years are valid. Apart from the striking feature of the differing reactions in various parts of France, the most outstanding is the very rapid decline of the death rate in France after the preliminary rise. This fall in the tuberculosis death rate is greater than for any other country in Europe. During the first years of the war the tuberculosis and the general death rates followed a similar course. But since 1943 the general death rate has remained higher than before the war; so the proportionate tuberculosis mortality in the department of Seine, for instance, went down from 13.5% in 1938 to 9.1% in 1945. For the whole of France it is now 6%, and this means in fact that it is approaching the level of relative importance that tuberculosis has in England as a public health problem. If we consider the pulmonary tuberculosis mortality separately we find an even more acute decline; the death rate from non-pulmonary tuberculosis was unchanged. It is important to note that this steep decline in the death rates from tuberculosis has been observed in most parts of the country; this is obvious in the most recent figures for separate large cities of France.

In England and Wales, as in Belgium and France, there was a rise in the first two years of the war, though less acute than in those countries. Obviously our experiences were less severe from many standpoints than those of the occupied countries, but in 1940 the air raids and the anticipated invasion, with evacuation of sanatoria from the danger areas and of hospitals to make room for air-raid casualties, combined to produce a situation highly favourable for the tubercle bacillus. The increase was 13% in the first two years. In this increase anxiety and overwork must have played an important part; there is evidence also that increased opportunities for infection were a major factor. The evacuation of hospitals and sanatoria, the black-out conditions, the overcrowding in homes because of air raids and billeting, the numbers of tuberculous patients drawn into industry, and the coming in contact with them of numbers of people who previously had led a relatively isolated life, must all have combined to increase infections greatly over the pre-war rates. There was in fact a marked increase among children under 5: between 1938 and 1941 deaths from respiratory tuberculosis went up 55% in boys and 105% in girls.

For meningitis in children up to 10 years there was an increase of 50%, and there is evidence that the majority of these infections were caused by the human bacillus. In mental hospitals in England and Wales, which already before the war had an alarmingly high tuberculosis mortality—nearly 1925. The rate increased by 140% to 901. Here [illegible] tuberculosis must have been low nutrition [illegible] 377 [illegible] with overcrowding. Since 1[illegible] the dominant factor in England and Wales [illegible] infection [illegible] have not reached the Denmark [illegible] death rates [illegible] pre-war trends had continued uninterrupted. In children under 5 the death rate has remained above the level reached before the war.

III. Countries in Which the Death Rates Rose Through the War Years to a Peak at the End of the War

In Fig. 6 are shown the trends in several countries; the rates are those for large cities, as with the exception of Holland the overall national rates are not known. All show

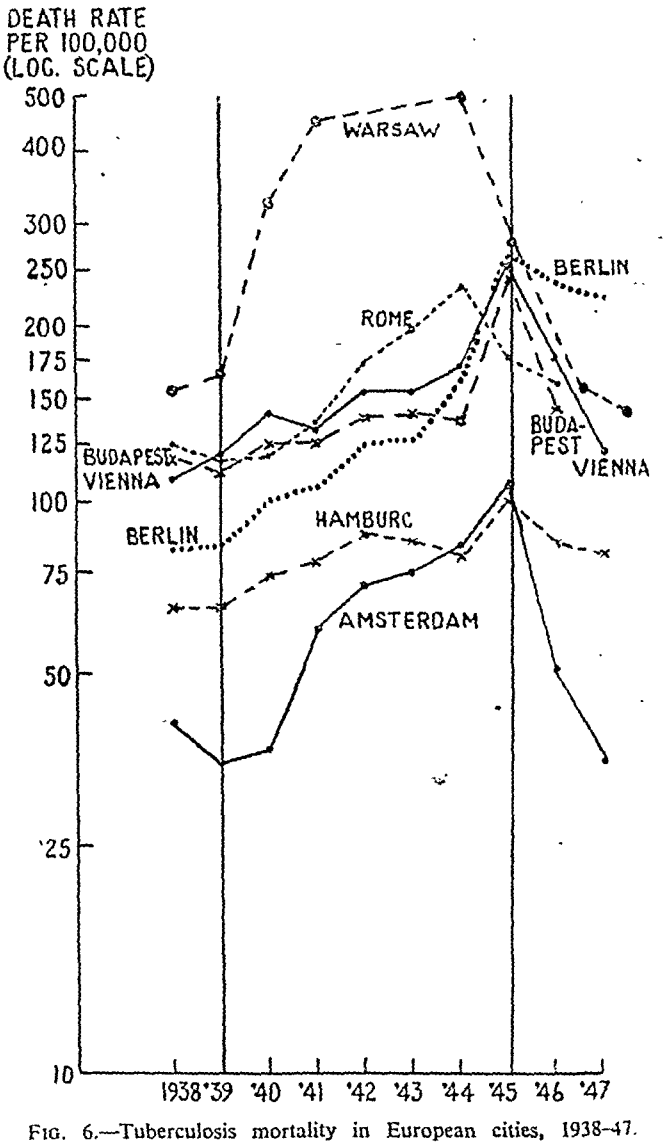


FIG. 6.—Tuberculosis mortality in European cities, 1938–47.

the same type of curve with an acute drop at the end. All are countries which were most severely affected in the final years of the war.

In Holland the rise was greater in Amsterdam than in the rest of the country—this is the more important as between the wars the rate in Amsterdam had declined to a lower figure. Between 1939 and 1945 it rose 208%, compared with the rise of 111% for the whole country. There is no doubt that the worst suffering in Holland was during the fighting in the final year. In Amsterdam many died of starvation. The deaths from all causes in the first half-year, which in 1939 numbered 3,736, totalled 9,701 in 1945. Deaths from infantile diarrhoea were 4 in 1939, 38 in 1944, and 255 in 1945.

In both Hungary and Austria there was a very acute rise at the end of the war. In Budapest the food situation

was not bad during the war, but there was chaos during the final year, and inflation with an acute food shortage. A very similar situation developed in Vienna. The highest mortality in Vienna was in the working-class boroughs; in one of the boroughs where there were the worst housing conditions the death rate was 322 in 1945. In both cities there was a sharp drop after 1945.

For Rome the peak of mortality was in 1944, and the death rate subsequently fell steeply. A study of the mortality in different parts of Italy reveals some interesting factors, reflecting here as in France the differences in conditions. The trends up to 1942 are very similar; by then there was an increase in tuberculosis deaths of 36–41% for respiratory tuberculosis, 21% for other tuberculosis. For cities of Southern Italy the mortality then went down gradually; we can recall that this part of the country was little affected by the fighting after the invasion. In Northern Italy there was a fall in 1943 and 1944 and another rise in 1945 corresponding with the campaign at the end of the war. But in Central Italy, where the most severe war conditions prevailed and for the longest period of time, the death rate rose steeply in 1943 and 1944 to a rate 130% above that of 1939. Subsequently there has been a drop, but in 1946 the rate (83 for the whole of Italy) was still above the pre-war figure: if the rate of decline in pre-war years had continued, mortality in 1946 would have been about 50.

In Germany also conditions were worst in the final years of the war; the aerial bombing, the disruption of public health activities, and the breakdown in food supplies must have contributed to produce the acute rise in 1945 after a moderate rise in the preceding war years. In all areas there has been a fall in mortality since 1945. The situation is much graver in Berlin than elsewhere. Among reasons given for the greater mortality in Berlin are: during the war, the effects of continual as opposed to sporadic raids, and since the war the food difficulties—much more serious than in the British and United States Zones—and particularly the fact that Berlin has been cut off from use of its sanatorium beds, most of which were outside the city. In this respect the Zones were relatively well placed; Berlin was left with a little over 5,500 beds, or 0.7 bed per death, compared with over 2 beds per death in the British Zone. The exceptional opportunities for hospital treatment of cases in the Zones may well be responsible for at least a part of the post-war decline in mortality. The tuberculosis mortality in the Western Zones of Germany is well below that of many other European countries, including Scotland and Ireland. The most recent figures for 1948 show a continuing fall in all areas, including Berlin, where the rate for the first half-year was 30% below that for the first half of 1947.

Poland is one of the countries which already before the war had a high death rate from tuberculosis. Figures for the whole country are not available, but we know that in the cities with one exception the rate was over 150 per 100,000. Despite wholesale destruction by the Germans, some records were preserved, and it has been possible to trace the course of the disease through the grim years of the occupation. Already by 1941 the mortality from tuberculosis in Warsaw had increased by nearly 200% over 1938, and in Lodz the increase was 80%. These are the worst recorded tuberculosis death rates that we found anywhere; there is sufficient in the conditions of the occupation to explain the magnitude of the rise. The rate persisted at a very high level, increasing further until the end of the war, since when there has been a rapid fall, and in all towns the rate is now well below the pre-war level. For combined figures of six main towns the most recent rate—for the year from mid-1947 to mid-1948—is 28% below the 1938 figure. In Katowice, a flourishing mining and industrial centre, the rate is now 63 compared with 101 pre-war.

There is less information on the mortality trends in Yugoslavia, but in the city of Ljubljana, which before the war had a particularly active tuberculosis control department, the death rate rose from 70 in 1940 to 263 in 1944.

Among the millions who died in concentration camps tuberculosis was only one of many causes contributing to death; but it was found in a very high proportion when the conditions in the camps were revealed at the liberation: 40% of necropsies at Dachau showed advanced tuberculosis. Of 64 cases of starvation studied in Belsen Hospital 27 had definite tuberculosis. At Buchenwald, Dachau, Nordhausen, and other camps, hundreds of tuberculous patients were taken out when the camps were liberated, many of them so ill that they died within a few days.

Tuberculosis trends in Scotland merit particular study, as this is the one country which, after having been seriously affected by the war, has shown no improvement in rates since the end of the war: there has even been a rise to a rate higher than the peak during wartime. Fig. 7 shows the death rates from respiratory tuberculosis between 1932 and 1946. The curve for the whole country shows the slow decline between 1932 and 1939 and the rise in the first year of the war; this level was maintained to 1945, since when there has been a further rise to a rate higher than in 1932. The combined rate for the large burghs shows a marked rise, and maintenance at a level well above 1932. The rate for the counties (excluding large burghs) showed a steeper decline in the pre-war years, a less marked but sustained increase during the war years, and in 1946 a rate still below the 1932 rate. The main part of the rise in Scotland is due to the rates in the cities, and it is interesting to look at a few of these specifically. Fig. 8 shows the death rates from respiratory tuberculosis from 1920 to 1947. In Aberdeen there was a fairly consistent fall through out the nineteen-twenties and nineteen-thirties, a rise during the

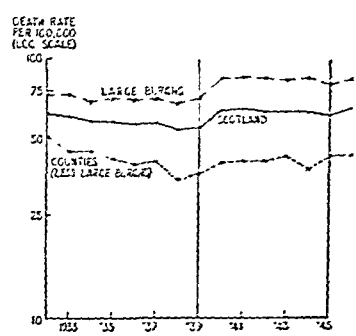

FIG. 7.—Death rates from respiratory tuberculosis, Scotland, 1932–46.

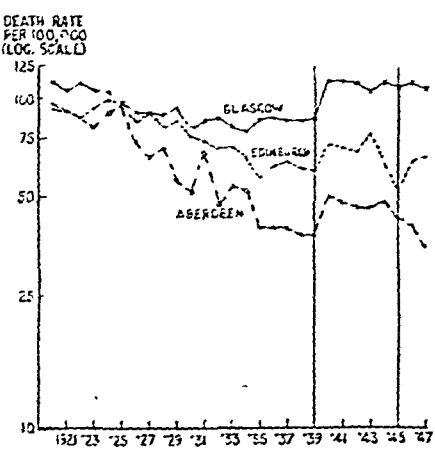

FIG. 8.—Death rates from respiratory tuberculosis, Scottish towns, 1920–47.

war, and a fall since then to a level below that for 1939; this is similar to what is happening in England. In Edinburgh there was a slower decline in the pre-war years, a fall at the end of the war, then a rise. It is Glasgow which presents the main problem: with its population of one million—i.e., one-fifth that of the whole of Scotland—it plays a large part in determining the overall trends. The first striking fact is that the decline in tuberculosis rates was arrested during the nineteen-thirties. Secondly, the wartime rise was steep and has been maintained at a level as high as the 1921 rate. There is at present a commission studying the causes of these trends, and one can only underline the differences between the trends in Scotland and those in the rest of the continent of Europe.

Age and Sex Analysis of Death Rates

An interesting phenomenon in the wartime rise in tuberculosis has been the predominance of the rise in men, except in Scotland (Fig. 9). In some countries, in fact, the rise was confined to males. Even in Denmark, where the overall rate from pulmonary tuberculosis had remained stationary at the low rate of 29 throughout the war, analysis shows that this rate was composed of a rate in males rising from 28 to 33, and in females falling from 30 to 25. Similar trends were observed in Holland.

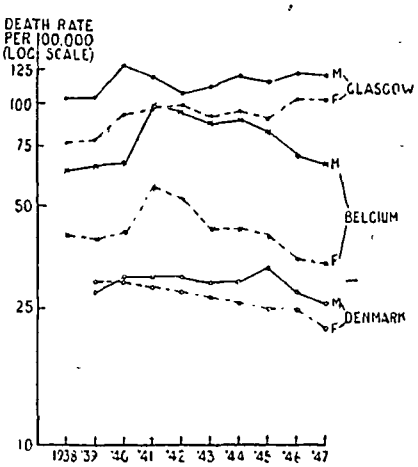

FIG. 9.—Respiratory tuberculosis death rates (male and female); showing predominance of the rise in men in Belgium and Denmark, compared with the trend in Glasgow.

In Belgium, where as in most other countries the rate in males was already higher before the war, the phenomenon is more striking. In 1941, at the peak of mortality, the increase over the 1938 rate was 49% in males and 36% in females. The subsequent decline was much slower in males: in 1944 the female rate had returned to the pre-war level, and by 1947 was 20% below; the male rate in 1944 was still 32% above the pre-war level, and did not reach it till 1947. There is much less difference between the sexes in the rates for non-pulmonary tuberculosis. In Italy there was a similar rise; whereas in 1939 the male death rate was 2% higher than in females, in 1946 it was 27% higher.

In France there was very little rise in the female rate in the years 1939–41, and a considerable drop subsequently at all ages. In males there was a very great increase at all ages, and a subsequent drop much below the 1935 rates. It is particularly marked in the 30–50 age group. The overall rise in the first two years of the war was 16% in females and 57% in males. A noteworthy feature of the remarkable fall in tuberculosis mortality in France is that it occurred in all age groups except young children and old people.

In Berlin, where as we have seen there was an alarming increase in tuberculosis, the increase was greater in men than in women, and occurred at all adult age groups. In Hamburg, if one compares the 1946 rate with that for 1939, in females there was no increase, whereas in males the rate was nearly 50% higher in 1946 than in 1939.

In Scotland, on the contrary, there has been a greater increase in females than in males (in 1946–7 the respiratory tuberculosis death rate was 19% higher in males, 32% higher in females, than at the outbreak of war). In fact, the exceptional rise of rate in women is the main feature of the persisting high rate in Scotland when compared with the rest of Europe. An analysis of the data in age groups shows that in females the increase was predominantly in young women. In men the increase was wholly in the older age groups.

Many possible causes have been suggested for the excessive rise of mortality in males in countries other than Scotland. Certainly in part it may be due to the selection by the Services of healthy non-tuberculous members of the young adult population. But where rates are calculated on the whole population this does not apply; and, moreover, we have seen that the older age groups showed a greater rise than those affected by military service. Deterioration in working conditions and participation in outside work in civil defence duties in this country or in resistance movements in other countries may have played a part. In this respect, however, it is interesting to note that in the mental hospitals in England and Wales the increase was greater in males than in females and that it has persisted in males at a level 60% above 1939, whereas in females it is now back at the 1939 level. There, either added exposure to infection or undernutrition, or both, must be responsible. It has been suggested elsewhere that reaction to malnutrition is more severe in males than in females, but definite proof of this is lacking.

It is interesting to look in rather more detail at the age-group trends in each of the sexes. In Fig. 10 for England and Wales, where the rates are adjusted to include non-civilians, one sees first that in females a peak at ages 20–24 is maintained, and that there is a fall in all age groups, whereas in males the rates are lower in 1947 than in 1939 at all ages except young children and the over-fifties. This is part of a phenomenon which is being increasingly noted in other countries—namely, the maintenance of the acutely peaked curve in females with a maximum at ages 15–24, though with falling rates, and in males the rounded curve with high rates at all adult ages but a peak gradually shifting towards the older age groups. This phenomenon of the

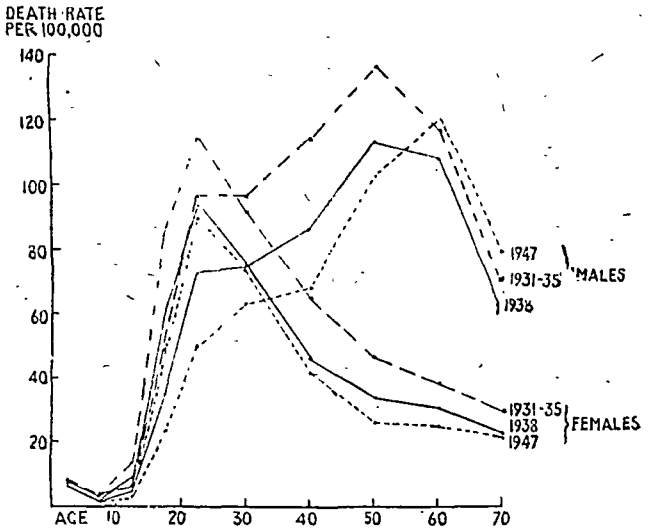

FIG. 10.—Tuberculosis mortality in England and Wales at various ages (male and female, and including non-civilians), in 1931–5, 1938, and 1947. Respiratory tuberculosis only.

shift of the peak to the older age groups in males has given rise to various hypotheses. A most interesting one is based on a statistical analysis of tuberculosis mortality in successive generations: the mortality in different age groups plotted on a generation basis shows little change in the type of curve through successive decades (Springett, personal communication).

Tuberculosis Morbidity

I have taken the tuberculosis death rate as the main index of tuberculosis trends. At present it is the most reliable index. Statistics regarding new cases diagnosed in dispensaries each year, or new notifications, or total cases known to the dispensaries at any one time are not lacking. But in the conditions of war these are practically valueless for comparative purposes, either for comparison between successive years in the same country or between different countries. Fig. 11 is characteristic. It shows for Belgium the dispensary case rate going up to a very high figure at a time when the death rate was well on the way down. Had that rise represented a true rise in morbidity there would have been a delay in the decline of the death rate or at least another rise later on. But it is clear from the accounts by the Belgian authorities themselves that, with the granting of double rations for the tuberculous at a time when rationing was very severe, the dispensaries were beset with people more or less asking to be diagnosed as tuberculous—and in the conditions of the occupation there was little reason why doctors should refuse. In France, too, the notification rate continued to rise at a time when the death rate was falling: in 1945 the total of new cases on the register was 45% above the 1938 figure, but the death rate was 20% below, and subsequently it continued to fall steeply.

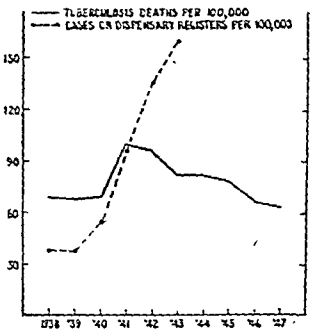

FIG. 11.—Morbidity and mortality statistics, Belgium, 1938–47.

The problem of assessment of tuberculosis prevalence by the morbidity rates has arisen again in the past two years in Germany. Alarming reports were issued pointing to a very acute rise in the numbers of notifications. It was said that, though the death rate was declining slightly, another rise would certainly occur. However, the death rate has continued to fall.

Thus even in the few countries in Europe where notification of tuberculosis is compulsory there may be very serious causes of error. The morbidity statistics may be of value in a country where tuberculosis is notifiable, where there is a well-defined and constant basis of notification, where the economic situation is not such as to influence the diagnosis, and at a time when new methods of examination are not being introduced. It is possible that much information may be derived from them in the future.

Results of mass radiography could conceivably provide more valid information concerning the prevalence of tuberculosis. No comparison can be made with pre-war prevalence, but comparison should be possible between different European countries, since, when properly employed, results should indicate what proportion of a community at any single time have lesions of pulmonary tuberculosis significant enough to require observation or treatment. The method is being extensively used now for the early detection of tuberculosis, and it is tempting, despite variations in diagnostic interpretation, to compare in detail the results obtained in different countries. There are some gross differences that one cannot ignore—between on the one hand the Scandinavian countries, France, Germany, and this country, with an incidence of about 3 to 5 per 1,000 of active tuberculosis requiring treatment, and, on the other hand, countries like Greece and Poland, with an incidence of corresponding lesions in 10 to 50 per 1,000 of the populations examined. Mass-radiography examination of Frenchmen returning from Germany in 1945 revealed pulmonary lesions in 1.5% of prisoners of war, 2.5% of men coming from labour camps, and 4.4% of men from concentration camps. There can be no doubt from present-day surveys that there is a very high prevalence of tuberculosis in Eastern European countries. At the present stage of development of this method, however, it is probably not justifiable to make more detailed comparisons.

Statistical Analysis. Conclusions

Looking back over this collection of statistics, there are at least three outstanding features about which there can be little doubt, despite the reservations regarding the absolute validity of some figures. One is that the wartime rise was closely related to the severity of war conditions; the second that the rise predominated in men; and the third that in nearly all European countries there has been an important fall in tuberculosis mortality since the end of the war.

The study of trends in different countries has shown that the increase in tuberculosis was related to deterioration in conditions so closely, in time and in gravity, as to constitute a remarkable index of the wartime tribulations of those countries. That tuberculosis prevalence is closely related to living conditions and nutrition is no new conception and has been shown in several studies of under-privileged communities. The incidence of tuberculosis discovered by mass radiography in Polish university students is on the same level as the incidence of lesions discovered in homeless destitutes of New York City (Edwards, 1940).

In some ways the disaster was not as great as in previous wars; this applies particularly to the countries where public health services had developed to a high degree between the two wars. In former years the health and social services in peacetime were barely adequate to maintain a perilous state of equilibrium, and the disaster of war would so upset the balance as to produce chaos. This time, in countries such as our own, after the first crisis with the evacuation of hospitals the health and social services were rapidly re-established, and measures designed to protect the people's health were extended well beyond those of peacetime. It is to the credit of those responsible for planning the health and food services of the country during and after the war that the wartime attack on health was relatively well resisted. On the other hand, where the social and health services were relatively undeveloped before the war, where already before the war there were very high tuberculosis rates—and this applies to many of the Eastern European countries—the wartime reaction was nothing less than catastrophic, and was made even more so by the conditions of the German occupation.

There has been much conjecture regarding the nature of the wartime rise. The additional deaths could be of patients who under normal conditions would have lived a little longer; they could be of those patients who would normally have overcome their disease and survived. In both events the main factor responsible would be the

deterioration of living conditions and of nutrition aggravating the prognosis of established disease. Or, thirdly, the deaths could be of persons who were being infected for the first time in greater numbers than normally because of increased exposure. No doubt in most countries there was a combination of all three factors.

In this respect the post-war fall, and in particular the rate of fall, is worth studying. Were the wartime rise due solely to the premature death of patients suffering from the disease we would expect a steep rise followed by a deeper fall, and it is possible that this may occur where conditions are severe enough to precipitate the death of patients with a bad prognosis, but not to provoke any great extension of the disease. This may partly explain the remarkable fall in France, but other factors must intervene also.* In nearly all other countries, where the pre-war decline was resumed at the same level or a higher level than would have been observed normally, it is obvious from the plotted rates for both world wars that there were many thousands of deaths from tuberculosis which would not have occurred but for the war. To what extent these were due in the main to aggravation of disease from which the patient normally would have recovered, and to what extent to new infections, must remain an open question.

We are far from a complete understanding of the nature of the wartime and post-war trends in tuberculosis. The uncertainty of our conclusions regarding widely differing trends, in for instance France, England, and Scotland, underlines the need for sounder and more detailed epidemiological study of tuberculosis in the future. Such study is at any time indispensable to a rational programme for eradication of the disease; it is particularly so at a time when our resources are limited, and action must be directed towards those groups of the community revealed in this way as being most susceptible to the disease. It will certainly be indispensable in the future when improvement in social services reaches the limit of reduction of tuberculosis by such means and we are left with the need for a real understanding of the disease if any further progress is to be made.

[The second lecture, with a list of references, will appear in our next issue.]

*One possible factor is the fall in consumption of alcohol since the introduction of rationing of wines and spirits in France during the war. This was followed by a marked fall in morbidity and mortality from diseases attributable to alcoholism, a fall not paralleled in any disease other than tuberculosis.

A residential college—the Midwife Teachers Training College—has been opened for midwives training for the Midwife Teachers Diploma awarded by the Central Midwives Board. The college is at High Coombe, Kingston Hill, Surrey, and will accommodate 16 students at a time for courses lasting six months. The first course is expected to begin in January, 1950. Intending candidates, who must satisfy the requirements laid down by the Rules (Section C) framed by the Central Midwives Board under the Midwives Acts, should apply for places to Mr. G. Thomas, Secretary, Midwife Teachers Training College Council, 72, Great Peter Street, London, S.W.1. Selected applicants will be required to give the council of the college a written undertaking that if they qualify they will serve as midwife teachers within the National Health Service for at least two years. The Minister of Health hopes that hospital boards and committees will encourage midwives likely to make good teachers to take advantage of these facilities. Suitable intending students should not be dissuaded from taking the course on the grounds that the hospital in which they are employed has no prospective vacancies for midwife teachers, since the scheme is intended to benefit the midwifery services as a whole.

RISK OF NEUROLOGICAL COMPLICATIONS IN PERNICIOUS ANAEMIA TREATED WITH FOLIC ACID

BY

M. C. G. ISRAËLS, M.D., M.Sc., F.R.C.P.

AND

JOHN F. WILKINSON, M.D., M.Sc., Ph.D., F.R.C.P.

(From the Department of Haematology, University and Royal Infirmary, Manchester)

The identification and synthesis of pteroyl-γ-glutamic acid (folic acid*) by Angier *et al.* (1945, 1946) led to the early recognition of its quite unexpected and remarkable effects in the treatment of pernicious anaemia (Moore *et al.*, 1945) and of nutritional macrocytic anaemia (Spies *et al.*, 1945).

The results in pernicious anaemia were very striking at first, as many workers reported, including ourselves (Wilkinson, Israëls, and Fletcher, 1946). It soon became evident, however, that even when the blood counts were restored to normal levels relapses were occurring, and signs of involvement of the peripheral nerves, such as paraesthesiae and numbness in the limbs, and of the spinal cord tracts, like ataxia and loss of vibration sense, might not be improved or might become worse.

Even more important, however, was the fact that some patients who had not previously shown signs of nervous system disturbances developed such signs, often very acutely, after being treated with folic acid for variable periods. Since 1946 several groups of workers have become aware of this disquieting fact, and in consequence the widespread enthusiasm for folic acid, at least for the treatment of pernicious anaemia, has been rapidly waning.

In Table I we have included all the available references to the development of subacute combined degeneration of the spinal cord in patients with pernicious anaemia, or the worsening of neurological symptoms already present, after treatment with pteroyl-γ-glutamic acid.

From a careful study of the various reports it was obvious that many of them referred to the same groups of cases, since some authors have published their results and cases in several journals, often without cross-references, and in some reports no details are given at all, other than

*In this paper folic acid is used synonymously with and refers to the synthetic pteroyl-γ-glutamic acid.

the bare statement relating to the occurrence of neurological complications in a group of patients. We have therefore inserted in the table the latest figures of each group of workers, omitting their earlier ones in other papers.

These reports suggest that, though folic acid treatment for patients with pernicious anaemia will lead in most cases to a satisfactory remission of the anaemia temporarily, there is a risk that damage to the spinal-cord tracts may continue and may show itself even after the blood counts have been restored to normal (Wilkinson, 1948, 1949). It is quite clear that pteroyl-γ-glutamic acid will not control disease of the central nervous system already present when treatment is begun. Previous estimates of the risk of the development of nervous system disturbance have varied in the larger groups from three out of 47 (Heinle and Welch, 1947; Heinle *et al.*, 1947) to 28 out of 38 (Spies *et al.*, 1948). Except for the later groups few of these patients have been observed for more than 12 months; most of them were under control for shorter periods. The pernicious-anaemia-posterolateral-sclerosis syndrome is notoriously slow to develop, so in order to obtain a better estimate of the risk involved in the use of synthetic pteroylglutamic acid we have since early in 1946 been observing closely a group of 20 pernicious-anaemia patients, either in relapse or having had no previous treatment, only three of whom had initial evidence of subacute combined degeneration of the spinal cord. We treated these patients with pteroyl-γ-glutamic acid alone until signs and symptoms of central nervous system disease appeared, or until there were signs of exacerbation of the disease initially present, and we have observed them all at frequent intervals: our intermediate results have been reported elsewhere (Wilkinson, Israëls, and Fletcher, 1946; Wilkinson, 1948, 1949). Our results after three years' observation of the group show that at the time of writing (May, 1949) only four of these patients are still well on folic acid treatment.

Illustrative Cases

The patients are divided into four groups: (1) Four patients with signs of disease of the nervous system developing acutely during treatment; (2) nine patients with signs of disease of the nervous system developing gradually during treatment; (3) three patients who had disease of the nervous system initially; and (4) four patients who had not developed signs of disease of the nervous system at the time of writing.

Details of groups 1, 2, and 3 are given in Table II, and of group 4 in Table III. Illustrative case records of patients in groups 1, 2, and 3 are given below. The patients in group 4 had the usual features of pernicious anaemia without neurological disturbance.

TABLE III.—*Group 4 Cases (No Signs of Disease of Nervous System)*

Case No.	Age	Sex	Initial Count		Period of Treatment (Months)	Final Count		Continuing Dose Folic Acid (mg. daily)

20	47	M	1·47	5·0	37	4·93	14·8	10

Group 1: Case 1

A married woman aged 63 was seen for the first time in May, 1946, complaining of dyspnoea, loss of weight, and increasing fatigue. She was pale and jaundiced, there was no enlargement of liver or spleen, and little abnormal was found in the heart and lungs. The arm and leg reflexes were normally active, plantar responses were flexor, and there were no subjective or objective sensory changes. A blood count showed: red cells, 1,640,000 per c.mm.; haemoglobin, 5.2 g. per 100 ml. The bone marrow was typically megaloblastic. There was complete achlorhydria gastrica.

She was admitted to hospital and given synthetic pteroyl-γ-glutamic acid, 20 mg. daily, by mouth. Her clinical condition and the anaemia improved steadily. After four weeks her red cells numbered 3,460,000 per c.mm. and the haemoglobin was 10.7 g. per 100 ml. Folic acid was reduced to 10 mg. daily, and after five months' treatment, when the haemoglobin was 14.2 g. per 100 ml., it was reduced to 2.5 mg. daily. This seemed to be too little, because after nine months the haemoglobin had fallen to 13.4 g. per 100 ml. and the red cells to 4,200,000 per c.mm. It was after nine months that she complained that her legs felt "as if she had wet stockings on," and examination showed that vibration sense was absent. The dose of folic acid was raised to 5 mg. daily. The nervous symptoms remained stationary until the 15th month, when within seven days she lost the use of her legs and became unable to walk. The blood count was then: red cells, 4,070,000 per c.mm.; haemoglobin, 11.8 g. per 100 ml.

Examination showed exaggerated reflexes, extensor plantar responses, absent vibration sense, and much-impaired position sense.

Folic acid treatment was immediately discontinued, and she was given liver extract intramuscularly and 30 g. of desiccated stomach daily by mouth. After one month her walking was improved, but the right plantar response was still extensor; after two months she was ambulant again and both plantar responses were flexor; after eight months all symptoms had disappeared and she has remained well since.

a = Stiffness and deformity of right arm present for 29 years, due to extrapyramidal lesion. *b* = Joint sense absent. *c* = Numbness of legs, absent vibration sense. *d* = Numbness and stiffness of fingers. Note: All patients had megaloblastic marrows initially and achlorhydria.

Group 2: Case 9

A joiner aged 58 was diagnosed as having pernicious anaemia some years before, but he had neglected treatment and when first seen his red cells had fallen to 1,210,000 per c.mm. and his haemoglobin to 3.9 g. per 100 ml. He was very pale and dyspnoeic, and had oedema of the feet and scrotum. The heart was not enlarged, but there was a generalized systolic murmur and occasional extrasystoles. His liver and spleen were slightly enlarged. In the central nervous system reflexes were normally active and plantar responses flexor; in spite of the oedema, sensation in the legs was normally appreciated. The bone marrow was megaloblastic, and achlorhydria was confirmed. He was given folic acid parenterally—at first 150 mg. intravenously, followed by 15 mg. intramuscularly on alternate days for 10 days; he was then given 20 mg. daily by mouth. He made a good recovery, and after two months, when his red cells numbered 4,200,000 per c.mm. and the haemoglobin was 11.6 g. per 100 ml., the folic acid was reduced to 10 mg. daily. After 4½ months' treatment the haemoglobin was 12.7 g. per 100 ml., and the dose was reduced to 5 mg. daily, and at nine months it was further reduced to 1.75 mg. daily, when his red cells numbered 5,060,000 per c.mm. and the haemoglobin was 13.8 g. per 100 ml. This latter dose was too small for maintenance: at 12 months the haemoglobin was only 13 g. per 100 ml., so the dose was raised to 2.5 mg. daily, and one month later to 10 mg. daily, when his red cells numbered 3,880,000 per c.mm. and the haemoglobin was 11.3 g. per 100 ml. At 14 months the red cells numbered 5,020,000 per c.mm. and the haemoglobin was 14.2 g. per 100 ml.; however, the first sign of disease of the nervous system appeared at this time—the patient complained of aching legs, but examination of the central nervous system revealed no objective abnormality.

The patient kept reasonably well until the 23rd month, when the blood count relapsed (red cells 2,930,000 per c.mm. and haemoglobin 8.8 g. per 100 ml.) and he had numbness and paraesthesiae in the arms and legs, and felt as if he were walking on cotton-wool.

Examination showed that his reflexes were still brisk and his plantar responses flexor, but vibration sense was now absent up to the knees and joint sense was impaired; Romberg's sign was present. He was given 30 g. of desiccated stomach daily, and he improved rapidly. Two months later his red cells were 4,920,000 per c.mm. and the haemoglobin was 13 g. per 100 ml. The only remaining neurological symptoms were slight paraesthesiae in the fingers.

Group 3: Case 15

A male cotton-spinner aged 46 had noticed that for the past five months his hands and fingers were becoming increasingly numb so that he could no longer handle the cotton threads; he also had some stiffness of the legs. He was not pale, and was well nourished; all tendon reflexes were brisk and equal on the two sides; the left plantar response was flexor, but the right was doubtful; cranial nerves were normal; vibration and joint sense were definitely present and normal. Other systems were normal. The blood count showed: red cells, 3,830,000 per c.mm.; haemoglobin, 13.3 g. per 100 ml. There was a definite megaloblastic marrow and an achlorhydria. The cerebrospinal fluid was not under pressure, proteins were 45 mg. per 100 ml., and there was slight globulin opalescence.

He was given folic acid, 20 mg. daily, but the blood count did not improve; after four weeks the red cells numbered 3,880,000 per c.mm. and the haemoglobin was still 13.3 g. per 100 ml.

Five weeks after starting folic acid treatment he complained that the numbness and paraesthesiae in the hands were much worse. Examination showed that vibration sense had now disappeared, but the reflexes were as before. Treatment with folic acid was therefore replaced with 30 g. of desiccated stomach. After one month of this he was much better, and his red cells numbered 4,740,000 per c.mm. and the haemoglobin was 14.2 g. per 100 ml. Ten months later he was back at work, but it was 16 months before all paraesthesiae had ceased and vibration sense had returned.

Discussion

We are not concerned here with the haematological and clinical effects of folic acid, which have been fully discussed elsewhere (Wilkinson, 1948, 1949), but only with its influence on the development of peripheral neuritis and subacute combined degeneration of the spinal cord in pernicious anaemia.

The accompanying Chart gives a graphic representation of the length of time during which treatment with pteroyl-γ-glutamic acid (folic acid) was given before the appearance of symptoms of subacute combined degeneration of the spinal cord. It is seen that the time of onset of neurological signs and symptoms of central nervous system disease is spread over a three-year period; apparently there is no time of special danger, nor is there any time after which the patient can be considered safe.

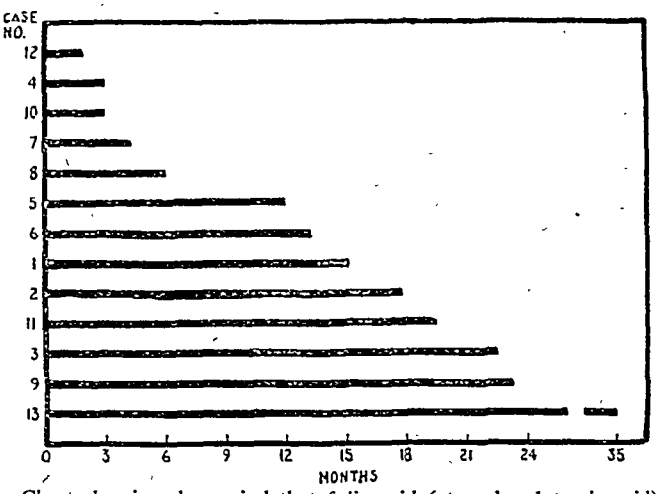

Chart showing the period that folic acid (pteroyl-γ-glutamic acid) treatment was given before the appearance of neurological signs made a change necessary.

The relevant information about these patients in Table II shows, disappointingly, that none of these observations make it possible to predict the likely onset of neurological complications. Of the four patients in group 1 the periods of treatment varied from 3 to 22½ months. Of the 13 patients in groups 1 and 2 six showed a falling haemoglobin level, and seven did not, while the haemoglobin levels varied from 8.8 to 14.6 g. per 100 ml.

The results therefore show that in a three-year period 80% of the patients who were being treated with folic acid had developed or had increased signs and symptoms of nervous system disease that could be quite quickly controlled in the early stages by treatment with intramuscular liver extracts or oral desiccated stomach preparations. Thus there is obviously serious risk that patients with pernicious anaemia treated solely with folic acid may develop signs of disturbance of the central nervous system, or that any initial cord involvement or peripheral neuritis may get worse.

Nevertheless, four patients have been well maintained on folic acid alone for up to three years without any apparent disadvantage. Is there, therefore, any place for folic acid in the treatment of pernicious anaemia? The facts reported here and by others emphasize in a new way the dissociation between the haematological and neurological parts of the pernicious anaemia syndrome. It is well known that the neurological syndrome can occur in the absence of anaemia. We can now see that a minority (20%) of patients with pernicious anaemia do not develop (at least after three years) disease of the nervous system when an agent (folic

acid) that corrects only the haematological disorder is used for treatment. But there seems to be no way of picking out this fortunate minority; certainly, initial absence of signs of nervous disease is no help. Consequently, it is our considered opinion that folic acid ordinarily should not be used in the treatment of pernicious anaemia, and never in subacute combined degeneration of the spinal cord. Very rarely it may be of temporary use in the treatment of a pernicious-anaemia patient who cannot take stomach preparations and is hypersensitive to parenteral liver extracts, until the patient has been desensitized, although oral liver extracts will usually get over this problem.

While the acute neurological syndrome described here and by others is rarely seen in the natural course of postero-lateral sclerosis with pernicious anaemia, nevertheless its apparent direct association with folic acid therapy raises the possibility of a folic-acid/anti-folic-acid mechanism in the maintenance of the integrity of the central nervous system; but we have as yet no definite evidence that folic acid causes organic lesions in the cord. At any rate, the action of folic acid on the neurological system is not the same as that of the liver principle, although its initial effect on the bone marrow and blood appears to be very similar. We have also yet to see a patient with pernicious anaemia who would not respond to haemopoietically active liver extracts but would respond to folic acid; it turns out that such patients always have some other disease, such as idiopathic steatorrhoea.

Therefore, whatever the circumstances, folic acid, if used at all, should be replaced by liver or stomach as soon as possible, and those patients having folic acid should be seen at frequent and regular intervals so that the onset of neurological complications can be corrected without delay.

It has been our view that, while folic acid must not be used in the treatment of the pernicious anaemia syndrome on account of the risk of producing postero-lateral sclerosis in patients otherwise free from neurological symptoms, its use was allowable in the treatment of other megaloblastic anaemias that do not develop cord lesions, like those occurring in sprue, steatorrhoea, and pregnancy. This must now be reconsidered carefully in view of the recent observation by Meyer (1948) that combined system disease occurred in a patient with macrocytic anaemia secondary to ulcerative colitis of long standing. After treatment with folic acid for 18 months he quite quickly developed ataxia, loss of vibration and position sense in the legs, and positive pyramidal signs. These neurological complications appeared when the patient's haemoglobin level was normal and his weight satisfactory. Davidson and Girdwood (1948) have also reported the onset of neurological signs in two patients with idiopathic steatorrhoea who were having folic acid treatment; the signs in these patients could have been due to peripheral neuritis, and no pyramidal lesion was detected. It is only reasonable to point out that this neurological complication of non-Addisonian types of anaemia is extremely rare.

Summary

A group of 20 patients with pernicious anaemia, either untreated cases or relapsed cases, have been treated with synthetic pteroyl-γ-glutamic acid (folic acid) alone; three had initial signs of subacute combined degeneration of the spinal cord.

In a three-year period 13 patients without initial neurological involvement developed signs and symptoms of subacute combined degeneration of the spinal cord which were relieved by changing the treatment to liver extracts or desiccated stomach preparations.

Three patients with initial neurological symptoms and signs became worse neurologically after folic acid therapy.

There was no specially dangerous point during folic acid treatment, for the times at which nervous-system complications became serious were evenly distributed over three years.

Neither the presence or absence of increasing anaemia nor the haemoglobin levels could be used to predict the likelihood of neurological complications.

Four patients are quite well after two to three years on doses of 5–20 mg. of folic acid daily, given orally.

The use of folic acid for the treatment of pernicious anaemia should be strictly limited to the rare cases of special difficulty.

Folic acid should never be given to patients with subacute combined degeneration of the spinal cord.

Delivering the chairman's address at the meeting of the Dental Board on May 11, Dr. Fish said that for the past year there had been a record decline in the total number of names on the *Dentists Register*. The figure was below that reached in 1939. About 90% of the dentists in active general practice in England and Wales, and a higher percentage of those in Scotland, were working in the National Health Service. When faced with more patients than he could comfortably treat, a dentist must do one of three things—add to his hours of work, refuse to see some patients, or speed up his work. He might even do all three. Probably most were now working longer hours than those recommended by the Spens Committee. Whether that added to their efficiency or to their enjoyment of life must remain an open question. Most dentists were in the dilemma that they must either refuse patients in need or hurry through the treatment of each in an effort to extend their services to all. The question was not whether they would condescend to work the Service but whether as individuals and as a profession they had the capacity for self-discipline, the ethical training, and the philosophy to rise to those heights of altruism which the Service demanded of them. For many there was no possibility of choice. The Service was their only means of livelihood. The success of the Service and the future of dentistry depended upon their willingness and capacity to sacrifice what might be legitimate personal gain for the salvation of their self-respect and the honour of their calling. Referring to the formation of dental companies under the influence of laymen, he said he did not think that any member of the profession should accept service under such conditions without the most careful consideration of what they implied.

AUREOMYCIN: A NEW TREATMENT FOR SYPHILIS?

BY

R. R. WILLCOX, M.B., B.S.

Physician in charge, Venereal Diseases Clinic, King Edward VII Hospital, Windsor; Senior Assistant, Venereal Diseases Department, St. Mary's Hospital, Paddington

Aureomycin, a yellowish crystalline substance prepared from *Streptomyces aureofaciens*, is dispensed in capsules containing 250 mg. of aureomycin hydrochloride and is administered by mouth. It has already been shown to be effective in rickettsial diseases such as Rocky Mountain fever (Ross *et al.*, 1948), in atypical pneumonia, in brucellosis (Spink *et al.*, 1948), and in certain eye conditions and urinary infections, as those due to *Aerobacter aerogenes* and *Streptococcus faecalis*, for which some consider that aureomycin is to be preferred to streptomycin and the sulphonamide group of drugs. It has considerable application to venereal disease. Finland *et al.* (1948) used it in 66 cases of gonorrhoea, with 49 definite and 11 doubtful successes and six failures Improvement was noted in two cases of penicillin- and sulphonamide-resistant non-specific urethritis. It is also of value in granuloma inguinale (Greenblatt *et al.*, 1948). In addition, Wright *et al.* (1948a, 1948b) have shown that it is effective in the virus disease of lymphogranuloma venereum.

The following case reports indicate that this antibiotic also has a powerful action upon the organism of syphilis. The patients were Bantu negroes with early syphilis, in Southern Rhodesia, and in all of them *Treponema pallidum* was demonstrable before treatment. As the supplies of aureomycin available were scanty and the prospects of an adequate follow-up problematical, it was considered expedient to treat a number with small, probably subcurative doses and to observe the effect by subsequent dark-field examination.

Case Reports

Case 1 (Seronegative Primary Syphilis).—A native from Portuguese East Africa had a typical indurated penile primary chancre with firm rubbery non-tender inguinal glands. The Wassermann and Kahn blood reactions were negative, but a dark-field examination of material taken from the sore showed *T. pallidum*. On May 18, 1949, he was given three 250-mg. capsules of aureomycin (Lederle) at intervals during 24 hours. Twenty-four hours after the starting of treatment the dark field still showed *T. pallidum*, although with greater difficulty. At 48 and 72 hours, however, none were recovered: at this stage he was given a course of penicillin.

Case 2 (Seropositive Primary Syphilis).—A male negro from Portuguese East Africa presented an indurated fraenal ulcer with a developing left inguinal bubo. Clinically the case resembled a mixed infection of syphilis and chancroid, and, although the dmelcos and Frei skin tests were negative, Ducrey's bacillus was seen in smears from the sore. The dark field, however, showed *T. pallidum*, and the Wassermann and Kahn blood reactions were positive. He was given five capsules of aureomycin orally over 29 hours (total 1,250 mg.). Twenty-four hours after the onset of treatment *T. pallidum* was still isolated by dark field, but dark-field examinations performed daily for the next 16 days were all negative. By the end of this time the sore had healed and the bubo resolved without additional treatment.

Case 3 (Seropositive Primary Syphilis).—A male negro from Portuguese East Africa was admitted with a paraphimosis and an indurated fraenal sore with typical syphilitic inguinal adenitis. *T. pallidum* was seen without difficulty in the dark field, and the Wassermann and Kahn blood reactions were positive. He was given three capsules of aureomycin daily for two days (total 1,500 mg.), and although the sore was still unhealed after 17 days no *T. pallidum* was observed at daily dark-field examinations during this time. A week later the sore had healed and the patient was discharged for surveillance.

Case 4 (Secondary Syphilis).—A Nyasaland negro attended with multiple perianal and peno-scrotal condylomata lata with enlarged non-painful inguinal glands. The dark field from the condylomata showed an abundance of *T. pallidum*, and the Wassermann and Kahn blood reactions were strongly positive. He was given one capsule of aureomycin orally three times a day for two days (total 1,500 mg.). The response was dramatic, and the lesions had healed completely by the fourth day. Daily dark-field examinations had been repeatedly negative.

Case 5 (Secondary Syphilis).—A female native of Southern Rhodesia was admitted with an indurated primary sore of the left labium majus, which was also oedematous. Secondary vulvar mucous patches and vulvar and perianal condylomata lata were also present, the whole being secondarily infected and evil-smelling. *T. pallidum* was seen without difficulty, and the Wassermann and Kahn blood reactions were markedly positive. She was given one capsule of aureomycin three times a day for two days (total 1,500 mg.), response being immediate. The daily dark-field examinations were negative for the ensuing four days, by which time the lesions had healed. She was kept under observation for a further three days; she was then discharged from hospital with instructions to attend as an out-patient. She returned, however, on the twelfth day with a relapse of the condylomata, and was then treated with penicillin.

Case 6 (Secondary Syphilis).—A female native of Southern Rhodesia was admitted with perivulvar and perianal condylomata lata, from which *T. pallidum* was obtained without difficulty. The blood Wassermann reaction was positive. She was given four capsules of aureomycin orally (total 1,000 mg.), and the lesions healed rapidly. Daily dark-field examinations were negative for the ensuing three days, and on the fourth the lesions had healed.

Case 7 (Secondary Syphilis).—A male South Rhodesian negro had a preputial sore from which *T. pallidum* was recovered and secondary condylomata lata on the scrotum. The blood Wassermann reaction was strongly positive. He was given three capsules of aureomycin orally on the first day and two on the second (total 1,250 mg.). Healing was rapid, being complete in four days, during which time daily dark-field examinations were negative.

Case 8 (Seronegative Primary Syphilis).—A male native of Southern Rhodesia had a giant fraenal chancre with typical syphilitic glands. The dark-field examination for *T. pallidum* was positive and the blood Wassermann reaction was negative. He was given six capsules of aureomycin orally in 48 hours (total 1,500 mg.). Daily dark-field examinations were negative during the next three days and the sore had nearly healed by the fourteenth day.

Case 9 (Secondary Syphilis).—A male South Rhodesian negro had an ulcerated prepuce with massive condylomata lata of the scrotum and inner thighs. *T. pallidum* was found on dark-field examination, and the blood Wassermann reaction was positive. He was given six capsules of aureomycin orally (1,500 mg.) over 48 hours. Although the dark field showed scanty *T. pallidum* at 24 hours, none was observed at two and three days. At two weeks, information was available to the effect that the condylomata had not disappeared but were quite dry.

Summary and Conclusions

Nine negro patients with early syphilis (two with seronegative primary syphilis, two with seropositive primary syphilis, and five with secondary syphilis) have been treated orally with aureomycin in doses of 750–1,500 mg. over 24–48 hours.

In six no *T. pallidum* was recovered at 24 hours, but in three the dark fields were positive at that time. In all, however, the dark fields were negative at 48 hours, and remained so daily for the periods over which observation was possible (3–17 days). Circumstances unfortunately prevented further observation.

Healing was most pronounced in the lesions of secondary syphilis, and in these the response was as dramatic as that obtained with penicillin, perhaps even more so. One case is known to have relapsed.

It is very unlikely that the small doses given were curative, although 250 mg. given four times a day for a week might well be.

It is concluded that aureomycin has a marked action upon human syphilis and opens up a new field of therapeutic investigation.

The above work was carried out during the course of a venereal-disease investigation conducted for the Health Department of the Government of Southern Rhodesia, to whom acknowledgments are due. I would also like to thank Dr A. J. V. Wilkins, Medical Officer of Health, Salisbury, Mr. Stephen Kennedy, and the staff of the lazaretto of that city for so freely offering facilities, and Mr. E. A. Boulter for his technical assistance.

COMMON DIFFICULTIES IN INFANT FEEDING*

BY

R. S. ILLINGWORTH, M.D., F.R.C.P., D.P.H., D.C.H.

Professor of Child Health, University of Sheffield

One of the effects of civilization is the fact that a large proportion of human infants have become parasites on the cow. The extent to which American infants rely on cow's milk for nutriment was recently shown by Bain (1948), who states that in the North-Eastern region of the United States only 23% of all babies are fully breast-fed on discharge from maternity units. In this country the Population Investigation Committee (1948) revealed interesting geographical variations in the incidence of breast-feeding. While 24% of women in Southport were fully breast-feeding their infants at two months, 85% in Lewisham were: the corresponding figures for Cornwall and West Sussex were 45% and 80% respectively.

According to the Ministry of Health Report (1944) 80% of all babies born in hospitals in this country are discharged fully breast-fed, but 95% of those born at home are fully breast-fed at the same age. Read (1949) claims that 98% of 516 women treated by him with Waller's methods were fully breast-feeding their infants on discharge, and Waller (1946) found that 79.3% of 300 consecutive primiparae in a South London district were fully breast-feeding their babies at the age of 6 months. Kao (1948) found that 95% of 26,647 Chinese out-patients were fully breast-feeding their infants.

The most probable explanation of these wide variations lies in differences in the technique of management of lactation. The figures suggest that in some places difficulties in breast-feeding are either prevented or successfully overcome, while in others they lead to artificial feeding. Artificial feeding itself leads to other difficulties, which in turn are preventable.

The theme of this paper is the suggestion that a high proportion of the difficulties in infant feeding are man-made and preventable, and that the cause of them lies in the medical attendant rather than in an inherent defect in mother or baby.

*Read in opening a discussion in the Section of Child Health at the Annual Meeting of the British Medical Association, Harrogate, 1949.

Difficulties in Mutual Adaptation of Mother and Baby

The difficulties which arise in the mutual adaptation of mother and child in the first few days are basically due to the nature of the child, but birth injury may lead to irritability or inertia in the baby and so to difficulties in adaptation. The irritable baby (who has not had a birth injury) who screams when brought to the breast, or who approaches the breast normally and then immediately withdraws his head and kicks and cries, is made worse by attempts to discipline him.

Rigid rules about the duration and frequency of feeds which do not allow adaptation to the needs of the individual, or attempts to force the child to take food when he does not want it, serve only to increase the difficulty. The baby particularly resents efforts to hold his head or to keep the limbs at his side with the aid of tight clothes or a blanket. The irritability is still further aggravated by the unnatural system, which still has its advocates, of keeping the baby in a nursery away from his mother, of not allowing her to cuddle her baby, and of bringing the baby to the mother only at that time which is considered the right one for his feed. The mother's fondling and cuddling before a feed may go a long way towards soothing him and enabling him to take his feed more easily. These difficulties of the first few days have been ably described by Middlemore (1941).

Difficulties in the Mother

Many of the difficulties in breast-feeding arise from inadequate preparation of the mother during pregnancy. Some obstetricians take little interest in the preparation of the mother for breast-feeding, and few paediatricians are given access to the mother before her baby is born. It is the paediatrician, however, who has to help the mother to surmount the difficulties in the puerperium which may result from this neglect.

Some failures of lactation are due to the mother's lack of desire to feed her baby. This may arise from ignorance of the value of breast-feeding to the baby, from a mistaken idea of the greater convenience of bottle-feeding, or from a desire for greater freedom to visit friends and places of entertainment. She may be afraid of the recurrence of a sore nipple or mastitis experienced in a previous pregnancy. She may have been told that lactation will take a great deal out of her. She may fear that breast-feeding will spoil her figure or her clothes. She may have failed to breast-feed previous children and be convinced that she will fail again. Most of these doubts and misunderstandings can be removed by discussing them with the mother during pregnancy, explaining to her the advantages of breast-feeding to the baby and to herself, and impressing her with the pleasure and satisfaction she will derive from it.

Inadequate or improper preparation of the breast during pregnancy may be another factor of importance in causing failure of lactation. Waller (1946) advocates that the mother should be taught to express a few drops of colostrum once a day for the last two or three months of pregnancy. He has shown in carefully controlled experiments

that this practice reduces the incidence of sore nipple, overdistension, and other feeding difficulties in the puerperium. Attention to a depressed nipple during pregnancy may prevent difficulties later. The Woolwich plastic nipple shield* advocated by Waller will help to elevate such a nipple. Inadequate attention to the mother's diet and failure to treat her anaemia may also be factors in causing failure of lactation.

Social factors, which are also man-made, play their part in causing failure of breast-feeding. Overcrowding, lack of privacy, the necessity of living with relations, overwork in the home due to lack of domestic help, the necessity of return to work in industry, queueing for food, all have a deleterious effect on breast-feeding. A woman who lives in lodgings is often compelled to give her baby a bottle to quieten it. The grandmother is frequently the cause of the baby being taken off the breast.

Worry

Worry is an important factor in the failure of lactation. Delay in the coming in of the milk, or ignorance of the normal time of the coming in, may worry the mother. Careless conversation between doctor and nurse about the baby is a common source of worry to her. Routine test feeds and frequent weighings almost inevitably cause the mother to worry about her ability to feed the baby. They are very apt to mislead the doctors and nurses and cause them to give complementary feeds—which go far to convince the mother that she will not have enough milk for the baby. Even though the mother is not told the result of the test feed by the nurse, she may obtain the information she wants by other means. The frequent weighings and the obvious concern of the doctor whether there is enough milk for the baby suggest to her the likelihood of a deficiency of milk. Test feeds should be used only for specific indications, when a feeding difficulty arises which suggests that the baby is not receiving enough milk, and in these circumstances they are essential.

Mothers are worried by the practice still found in some hospitals of keeping the baby in the nursery instead of at her bedside. Fields and Rose (1948) and others have shown that a mother has a much better chance of breast-feeding her baby if he is kept at her bedside night and day and not in a nursery. When the mother hears crying at the other end of the corridor she fears that it is her baby and that he is not receiving the attention he demands. She wants to cuddle, kiss, and admire her baby, for whom she has been waiting so long, but she is not allowed even to see him except at feeding time, five or six times a day. She is not given a chance to get used to handling him—to change the napkin and bath him—and she worries about her ability to manage him when she gets home.

The early discharge from hospital, necessitated by shortage of beds and nursing staff, means that she is discharged before lactation is established, and when she gets home there is often a gap of several days before the midwife or health visitor comes to help her in her difficulties. The paediatric registrar from the maternity hospital ought to be able to visit her in her home and give her the advice which she needs.

Insufficiency of Milk

By far the commonest cause of failure of lactation is insufficiency of milk. In a considerable proportion of cases, however, insufficiency is wrongly diagnosed or results from mismanagement. Those doctors and nurses who wrongly rely on scales to provide the only guide to the progress of the infant are often misled into giving complementary feeds when they are totally unnecessary. Many are ignorant of the normal rate at which milk comes in, and expect every baby to receive 2½ oz. per lb. (19.4 ml. per kg.) from the first day, whereas frequently the mother can give only the equivalent of ¼ oz. per lb. (5.7 ml. per kg.) on the fourth day, 1¼ oz. (13.5 ml. per kg.) by the seventh day, and it is not till the tenth day or later that she can give the full 2½ oz. per lb. required to give most babies a normal weight gain. Routine test feeds are done in some hospitals at every feed. They waste a great deal of the nurse's time and take her away from important nursing duties. In the home they waste the mother's time and inevitably lead to worry. I recently saw a child who had been given a test weighing at every feed every day for nine months.

Insistence on a rapid recovery of the physiological weight loss in the newborn period and on a rapid gain in weight is another potent cause of complementary feeding. Complementary feeds, if given unnecessarily, are apt to reduce the baby's desire for the breast and so to reduce the emptying of the breast, which in turn leads to failure of milk production. Some advise that a complementary feed in the newborn period should always be given by a spoon rather than a bottle because some babies may prefer a bottle to the breast. Certainly in the first week complementary feeding should be so exceptional that no nurse in a hospital unless specially trained should be allowed to give one without the permission of the paediatrician. Nurses and doctors worry unduly about the harm which will befall the baby if it does not gain weight normally in the first few days of its life. They pay too little attention to other signs of well-being in the baby—the appearance, tone, and contentment of the baby—and too much to the weight.

The commonest time for lactation to fail is about the tenth day, when the mother first returns to work in the home. The normal falling off of milk production at this time is only temporary, and if the baby is tided over this period and, if really necessary, given judicious and never excessive complementary feeds, milk production usually returns to normal in two or three days.

A common omission in the treatment of slight insufficiency of milk is failure to empty the breast by expression after feeds. The milk so expressed may be enough to make up for the deficiency in the baby, and the complete emptying of the breast stimulates it to greater milk production.

The stimulus to milk production is lost by two other bad practices: the giving of supplementary feeds, and the use of only one breast at each feed. In either case the effect is the same—incomplete emptying of the breast for long periods, with consequent decreased milk production.

Another potent cause of the failure of breast-feeding is the ready availability of artificial feeds. Much could be achieved for positive health by all the time and money which is spent by nursing, voluntary, clerical, accountant, and transport staff in supplying tins of milk. There would be much more breast-feeding of infants if artificial feeds were not so readily obtainable. I recall the story of a midwife who, when almost at term, was seen to collect twelve tins of dried milk from the clinic.

Care of the Breast

Mismanagement of overdistension of the breast is said by Waller (1946, 1947) to be one of the principal causes of the failure of lactation. Severe overdistension leads to involution of the breast and so to artificial feeding. It

*Made by Allen and Hanburys, Ltd.

causes severe pain to the mother, and this alone adversely affects the milk supply. The baby is unable to obtain the milk partly because he cannot get his jaws behind the nipple, and he will damage the nipple by sucking it. It predisposes to infection, and so to mastitis and abscess. The condition tends to be neglected in maternity units; stilboestrol is withheld until too late, and manual expression of milk to relieve the distension is often half-hearted and performed only once or twice, so that the breast is not emptied. Stilboestrol should be given promptly in cases of unduly rapid filling which causes overdistension. The dosage in the moderate case should be 5 mg. four-hourly. It is unusual to require more than three or four doses, and if the drug is continued longer than is necessary it will stop milk production entirely.

Soreness and cracking of the nipple is another difficulty in infant feeding which is usually preventable. They may be caused by the application of hardening agents to the nipple, such as spirit, and by scrubbing the nipple with a brush. Attempts to pull off dried secretions, instead of soaking them off with saline, may cause abrasions. They may be caused by leaving the baby to suck too long on the breast in the first day or two, before the milk comes in, or later by leaving the baby too long on the breast so that he sucks long after he has emptied the breast of milk. They are caused by allowing the baby to suck on a severely overdistended breast. They may be due to faulty hygiene.

A mature baby may approximate his jaws so tightly round the areola that he creates a vacuum, and if he is pulled off without first breaking the vacuum by insertion of the finger into the angle of his mouth he may damage the nipple. All too often the sore nipple is neglected and treatment is not given. If the slightest abrasion can be detected with the hand lens the baby should be taken off the affected breast and given the milk which is expressed at the ordinary feed times. Penicillin cream should be applied to the nipple, and the baby returned to the breast when in about forty-eight hours it is healed. Neglect of a sore nipple causes a great deal of pain and worry to the mother, and may lead to mastitis and abscess formation.

A breast abscess should be regarded as a disgrace in any maternity unit, and it will not be discussed here.

Difficulties in the Baby

Excessive Crying

This is usually considered to be a sign that the baby is not getting enough milk. That diagnosis is often correct, but it is more often wrong. Doctors and nurses are far too ready to diagnose insufficiency without any proof of the correctness of the diagnosis. It is a thoroughly bad practice to take the baby off the breast without confirming the diagnosis by test feeds.

Many other babies are taken off the breast on the grounds that the milk is not suiting him, is too rich, or is watery and not strong enough. These diagnoses are always wrong and should therefore never be made. I have recently seen seven babies who were put on to the bottle because it was thought that the mothers' milk looked watery.

The many other causes of excessive crying are often overlooked. One of the commonest is a rigid feeding schedule which takes no note of the needs of the individual. It is irrational to feed the baby strictly by the alarm clock. Such a method presupposes that babies are not individuals but are all alike. It presupposes that they have the same stomach-emptying time, the same degree of gastric acidity, the same temperament, and the same degree of activity. It ignores the wide changes of temperature characteristic of the British climate. It ignores the fact that babies have rest periods and periods of activity, and that activity causes hunger and thirst.

Gesell and Ilg (1937) and Aldrich and Hewitt (1947) have done many babies a great service by advocating the self-demand schedule, a rational method of infant feeding now widely practised throughout the United States. I have never yet seen any difficulties arising from it, but I have seen it solve very many feeding difficulties which arose from rigidity of method. Even if one does not go all the way in allowing complete freedom for the baby to choose its feed time, one should certainly advise the mother to use considerable elasticity in the feeding schedule and adjust it so far as she possibly can to the needs of her child. She should not waken the child for a feed. She must realize that the smaller the baby the more often it is likely to want to be fed. She should not give fluids between feeds because it is crying for food; instead she should adjust the frequency of the feeds to the baby's requirements. She should certainly be advised to feed the baby in the night in the first month or two when he wants it. Refusal to feed the baby in the night is a potent cause of excessive crying and of loss of sleep to mother and father.

Other causes of excessive crying are overclothing, neglect, loneliness, and lack of cuddling. The worst case of prickly heat which I have seen in this country was that of a baby who was brought to me on a particularly cold winter's day for excessive crying. The child was grossly overclothed and sweating profusely. Tight clothes which prevent free movements of the limbs may cause a baby to cry. Failure to change the napkin when it is wet is an obvious cause of unhappiness. A very common cause of excessive crying is loneliness and boredom.

Many mothers have the entirely erroneous belief that they will spoil a baby if they pick him up when he cries. Some have learnt a little about what psychologists call "overstimulation." They certainly will not spoil him unless they carry it out to excess. In the older baby the crying is frequently due to nothing but boredom, the baby being left outside in the pram for many hours a day, often without any toys, when he has learnt new skills—manipulation, sitting, or standing, which he is not given the opportunity of practising.

Rigidity in the duration of the feed is another cause of excessive crying. Those who advocate a fixed time on the breast for all babies presuppose that all babies suck at the same speed and that all breasts are the same. The duration of the feed is an individual matter. It is wrong to instruct all mothers to feed their babies exactly ten minutes at each breast. After the first two or three weeks most babies obtain all the milk they want in about five minutes at each breast. A very common cause of wind and colic is leaving the baby to suck too long on a breast. When the breast is empty sucking inevitably causes air swallowing.

Still another manifestation of wrongful rigidity of ideas concerns the quantity of milk the baby should take. Many doctors ascribe excessive crying and other feeding difficulties in the breast-fed baby to overfeeding. If they do a test feed and find that it is getting more than 2½ oz. per lb. (19.4 ml. per kg.) they feel that their diagnosis is confirmed. This diagnosis is almost always wrong. I have yet to see a baby whose symptoms are due to its taking too much from the breast. Not all babies are satisfied with the normal 2½ oz. per lb., and not all babies will show a satisfactory weekly gain in weight on that amount. The baby knows how much he needs.

Further Difficulties

Inadequate Weight Gain.—This is by no means always due to insufficiency of milk. It may be due to dehydration from excessive clothing. I was recently asked to see a baby who would not gain weight in spite of the fact that he was receiving an adequate supply of milk and that no organic disease could be found. The temperature of his room was about 80° F. (26.7° C.). The baby was covered with fifteen layers of clothes, including four layers of blankets. When the baby was suitably clothed the weight gain was normal. Defective weight gain may be due to a low-grade infection of the umbilicus, skin, finger, or nose. It may be due to separation from the mother in hospital and consequent loneliness and excessive crying. It is hoped that all children's units of the future will cater for the admission of the mother to the same room as her baby. Just when the baby most needs his mother, when he is ill or in pain, he is deprived of her love and cuddling, and he is left alone more than he has ever been left before.

Diarrhoea.—I have recently seen six babies who were taken off the breast on account of diarrhoea. In each case the diarrhoea was due to the mother taking certain purgatives which affect the breast milk—senna, aloes, cascara, or rhubarb. Many babies are thought to have gastro-enteritis or some form of protein or carbohydrate dyspepsia because of loose green stools which in fact are due to constipation arising from severe underfeeding. Many other babies are thought to have diarrhoea when in fact their stools are the normal loose stools of the fully breast-fed infant. Gastro-enteritis is an extremely rare cause of diarrhoea in the breast-fed baby.

Constipation.—True constipation in a fully breast-fed infant is usually due to insufficiency of milk. In a large proportion of babies brought up for this complaint, however, the motions are normal, but the mother is worried about their infrequency. It is perfectly normal for some breast-fed babies to have a motion only every four to five days. If the child is well and gaining weight normally and the motions are not hard, no treatment of any kind is necessary. I saw an infant 24 hours old who had been given an enema by the doctor for constipation.

Vomiting.—Many babies are thought to be vomiting, whereas they are merely posseting or bringing a little milk up with wind. Many babies are taken off the breast on account of vomiting. This is always a wrong thing to do, unless the vomiting is due to severe flatulence arising from insufficiency of milk. I have recently seen seven cases of congenital pyloric stenosis in which the baby had been put on to artificial foods because of vomiting, it being thought that the breast milk was "not suiting" the baby. In every case the vomiting persisted.

Flatulence.—More often than not flatulence is thought to be the cause of the baby's excessive crying and other symptoms, and very often the diagnosis is incorrect. Flatulence may, however, be caused by leaving the baby to suck on the breast too long or by insufficiency of milk. The latter diagnosis should be confirmed by test feeds.

Other Man-made Difficulties in the Breast-fed Baby.—Soreness of the mouth and thrush may be caused by cleaning the mouth of the newborn with swabs or by giving the baby a "dummy." A variety of infections may be caused by inadequate hygiene. Prematurity, with all its associated feeding difficulties, may be due to poor nutrition, obstetrical procedures, and other factors. Inertia in the newborn, leading to difficulty in breast-feeding, may be due to obstetrical procedures and to improper use of analgesics. Some babies have to be taken off the breast because of admission to a hospital which has no accommodation for a nursing mother. Others are taken off the breast on account of congenital haemolytic anaemia. Cathie (1947) showed that this was a wrong practice. Others are taken off unnecessarily because of the onset of menstruation.

Some Difficulties in the Artificially Fed Baby

Many of the difficulties which occur in the breast-fed baby also apply to the artificially fed baby. In addition certain special difficulties may occur.

Excessive flatulence and therefore colic is often due to the hole in the teat being too small. I saw a case of excessive flatulence of very recent onset in a 6-months-old baby: it was due to the fact that the mother had filled the feeding bottle with sago pudding and expected the baby to suck it out through the ordinary teat. Flatulence is also commonly due to leaving the baby to feed himself from a bottle propped up on a pillow. This causes him to swallow air for two reasons: he may create a vacuum in the bottle, and when the teat flattens in consequence he continues to suck it, so that he merely swallows air. It may also be due to the teat not being kept filled with milk, with the result that the baby swallows a mixture of air and milk.

Constipation is usually due to underfeeding. It may also be due to insufficiency of fluid or to failure to add sugar to those dried foods which do not contain added sugar, such as National Dried Milk.

Diarrhoea may be due to an infection such as gastro-enteritis or to adding sugar to a dried food which already has a high carbohydrate content. Diarrhoea must be distinguished from the loose green constipation stools already mentioned.

Vomiting may be due to improper mixing of the milk or to excessive flatulence. It is occasionally due to the hole in the teat being too large so that the baby gets the food down too quickly.

Failure to gain weight satisfactorily is usually due to underfeeding, but it may be due to infections or other organic disease. It may be due to measuring dried milk with a teaspoon which gives much less than the expected drachm (3.5 ml.), or to excessive dilution of the milk, either deliberately or because of the use of a tablespoon as a measure of ½ oz. (14 ml.) (many tablespoons measure ¾ oz. (21 ml.) or more). It may be due to following the instructions on the packet instead of adjusting the quantity of food to the needs of the individual. Very exceptionally it may be due to overfeeding. Overfeeding on the bottle can occur, but it is rare. It is certainly not nearly as common as Gibbens (1949) suggests. He is quoted as making the assertion that nine-tenths of all diseases in infancy and childhood are due to overfeeding. In fact most babies know when they have had enough, and overfeeding is an extremely rare finding in infants. It must be remembered that some babies require more than the calculated requirement to make them gain weight normally.

A common practice in the face of these feeding difficulties is to change the feeds in order to try to find a particular food which will "suit" the baby. This is a bad practice. The modern dried foods are so good that any of them if given properly and in reasonable quantity will cause most babies to thrive. Some cause other than unsuitability of a particular brand of milk should always be sought for the child's symptoms.

Difficulties in Weaning

Most of these are due to mismanagement. The commonest difficulties arise from trying to force the baby to

take food which he does not want. A determined baby will not tolerate such forcing. Attempts to give solids before the baby can chew may lead to vomiting. When a baby refuses the food offered it is a good plan to offer him a breast-feed first and then try the solid food after the breast-feed. When he gets used to it the breast-feed is stopped. The same applies to the baby who spits out the cod-liver oil and defies all efforts to give it to him. He will often take it at the end of a breast-feed without difficulty. A baby's crying and fussing during a feed is apt to be considered mere naughtiness, when in fact it is due to thirst, a soiled napkin, fatigue, or teething. It may be due to his desire to feed himself, or to a desire to use a cup instead of a bottle. Attempts to force the child to feed when he does not want it will certainly increase the difficulty. Many mothers are worried by the normal falling off of the weekly weight gain after the first six months, and so of his appetite. If the mother tries to force him to take extra food he will certainly refuse it. The more anxious and fussy the mother, the greater the difficulties which arise. The calm, patient mother who does not force the baby to take food against his will rarely has serious difficulty in feeding her baby.

Conclusions

A very large proportion of feeding difficulties are man-made. They arise from failure to prevent difficulties, from ignorance of the normal variations, and from rigidity and inelasticity in infant feeding instead of adapting the method of feeding to the needs of the individual. Other difficulties arise from the smattering of knowledge possessed by many about nutrition. Ultimately most of the difficulties in infant feeding can be ascribed to the inadequate training of doctors and nurses in the practical details of infant feeding and to the concentration in their teaching on the rare and the obscure, and on complex laboratory investigation and procedure, instead of on the really common problems which they will meet every day in general practice.

Within the next six or eight months the Northern Ireland Tuberculosis Authority hopes to have an additional 200 beds, including 116 for children. Dame Dehra Parker, Minister of Health and Local Government, stated recently that there were 1,381 cases of tuberculosis undergoing treatment in hospital, and that the number awaiting admission was 625. She added that there were now 248 more beds available than on September 1, 1947, when the Authority assumed all functions in connexion with tuberculosis services. The use of sleeping shelters at the homes of patients in suitable circumstances was being encouraged. At present 124 shelters were in use, and approval had been given to the provision of a further 50.

ANTIHISTAMINES IN THE TREATMENT OF NAUSEA AND VOMITING OF PREGNANCY

REPORT ON A CLINICAL INVESTIGATION

BY

T. DOUGRAY, M.B., Ch.B., M.R.C.O.G.

Obstetrician, St. Chad's Hospital, Birmingham; Obstetrician, County Borough of Smethwick

Nausea and vomiting of varying degree occur so often during pregnancy as to be accepted by the patient and her attendant as normal accompaniments of that condition. In some cases, however, in the absence of adequate treatment the vomiting becomes progressive, leading eventually to a complete intolerance of all foods and liquids.

Apart from those cases in which the sickness is associated with disorders of the urinary and gastro-intestinal systems, etc., little is known regarding the origin of the nausea and vomiting of pregnancy, although most clinicians seem to accept neurosis as an aetiological factor of considerable importance. Theories have been advanced which relate the condition to endocrine upsets and dietetic deficiencies; and the usual occurrence of the sickness during the period of placental development has led to speculation on the possible part played by the placenta in producing it. The most interesting hypotheses are those which consider that vomiting of pregnancy is an allergic reaction to albumin of ovo-placental origin, and that it is caused by toxic placental products, such as peptone, guanidine, and histamine, liberated into the blood stream by the activity of the trophoblast.

The conception that histamine might be an important aetiological factor was advanced by Hofbauer in 1926, and Kapeller-Adler (1941) has revived interest in this work. She has investigated the histidine-histamine metabolism in normal and pathological pregnancies. From her results she concludes that the toxaemias of late pregnancy are probably manifestations of histamine intoxication, and that the disorders of the early months, such as morning sickness, excessive salivation, dyspepsia, and headache, may indicate a smaller degree of such intoxication.

The encouraging results obtained from the application of antihistamine drugs to the albuminuria of acute nephritis led to an attempt to determine whether or not the onset of albuminuria as a manifestation of toxaemia could be averted by the use of these drugs in pregnancy. It was soon found that patients who complained of nausea and vomiting experienced relief from their symptoms during the administration of the antihistamine drugs. The response obtained, particularly in cases in which other measures had failed, was so striking that it was decided to carry out a fuller investigation of the therapeutic potentialities of the antihistamines in this condition.

Present Investigation

This clinical investigation was carried out during the period from January 1, 1948, to March 31, 1949, when a total number of 1,816 new patients attended the antenatal clinics of the Public Health Department of the County Borough of Smethwick. In the early part of the investigation observations were made on the effect of an antihistamine drug on patients whose nausea and/or vomiting did not respond to the therapeutic measures generally employed in obstetrics. These measures consisted in advice

on diet, such as the partaking of frequent small meals with abundant carbohydrate, the elimination of fried foods from the diet, and the avoidance of items such as tea and coffee, which in some instances seemed to aggravate the vomiting. All patients were advised to try the effect of eating a biscuit or two before rising from bed. "Marmite," yeast tablets, and dilute hydrochloric acid were also used, either singly or, in certain cases, in combination. The use of the antihistamines as primary agents in treatment was advocated later as the effects of their application were noted. Furthermore, as confidence in the drug was gained—having particular regard to the fact that no untoward reactions of any kind concerning the pregnancy itself were noted—it was found possible in some cases to give a larger therapeutic dose. The drugs used in the investigation were "anthisan" and later, when it became available, "phenergan."

The dosage of anthisan originally employed was one 0.1-g. tablet morning and evening, and this dosage was gradually increased until the drug was being given as a routine five or six times daily. The majority of the cases whose symptoms were not relieved completely by anthisan treatment occurred in the early stages of the investigation, when the smaller doses were given. This gave the impression that a stronger antihistamine drug would lead to better results, and accordingly, when phenergan became available for clinical trial in the latter part of the investigation, it was used in preference to anthisan. In most of the cases a daily dose of one 0.025-g. tablet three times a day proved to be sufficient to relieve symptoms. A few cases required a heavier dose, and in one case (No. 4, below) seven tablets were given daily to control the vomiting. The efficacy of the drug is dependent on the dosage employed, and its effect seems to be cumulative. It was found that the nausea and vomiting were most often relieved within two or three days of starting the drug, and treatment was continued for a period of several weeks to avoid relapse. It was usually possible to discontinue the drug after three or four weeks, but several cases were recorded in which the nausea and vomiting recurred, necessitating a further course of treatment. The chief side-effect noted with both drugs was drowsiness, and in those cases in which the effect was marked 5 mg. of amphetamine sulphate was sufficient to counteract this. The following is a summary of the results.

Total No. of cases	1,816
No. complaining of nausea and/or vomiting	899
No. treated with antihistamine drugs	94
Results of treatment:	
Cure	78 (83%)
Improvement	4 (4%)
Failure	12 (13%)

The use of the drug is illustrated in the following case records.

Case Reports

Case 1.—Mrs. A., aged 25, attended the antenatal clinic during the thirteenth week of her second pregnancy. She had suffered from severe morning sickness during the first pregnancy, the vomiting having continued intermittently until term was reached. She again complained of severe morning sickness, and was advised regarding her diet and the necessity for regular bowel action. When seen again four weeks later, however, she was no better and had lost 3 lb. 12 oz. (1.7 kg.) in weight. Anthisan, one 0.1-g. tablet three times daily, was prescribed for her, and after two weeks of treatment her sickness had disappeared completely. The drug was discontinued and she remained well for a period of four weeks, when vomiting of a milder type recurred. The drug was therefore prescribed again for a period of one week, after which the vomiting ceased entirely. Her convalescence from the vomiting the pregnancy remained normal throughout and culminated at term in the spontaneous delivery of a healthy female infant of 6 lb. 8 oz. (2.95 kg.).

Case 2.—Mrs. B., aged 38, attended the antenatal clinic in the ninth week of her seventh pregnancy. She complained of severe sickness, which occurred intermittently on several occasions each day, and stated that she had suffered thus throughout each of her pregnancies. She was given advice on general dietetic measures, and the retrodisplaced uterus was manually corrected, a Hodge pessary being inserted to maintain it in position. One week later, however, she was no better, and anthisan, one 0.1-g. tablet five times daily, was prescribed for her. At the end of one week of this treatment her sickness had disappeared entirely. The drug was then discontinued and the patient remained free of this troublesome complaint for the remainder of the pregnancy. She delivered herself spontaneously at term of a healthy male child weighing 8 lb. 10 oz. (3.9 kg.).

Case 3.—Mrs. C., aged 32, attended the antenatal clinic during the seventh week of her third pregnancy. Her two previous pregnancies had been unsuccessful, having terminated at nine weeks and eleven weeks respectively. She now stated that she had been forced to come to the clinic earlier than she had intended because of the severity of her sickness, which caused her constant trouble during the day. Phenergan was prescribed for her—one 0.025-g. tablet morning and evening. She reported a considerable improvement in her condition after four days of this treatment, and she was now sick only once each evening. The dosage was increased to three tablets a day, and this brought complete relief from her symptoms. The treatment was discontinued four weeks after her first visit. She remained well for a further three weeks, when the vomiting recurred, necessitating a further course of treatment for two weeks. Since then she has been perfectly well, and is now within four weeks of her expected date of delivery. The course of her pregnancy has otherwise been normal.

Case 4

The following case record, whilst not occurring within the above investigation, is included because of its unusual interest.

Mrs. X., aged 34, attended the gynaecological clinic in January, 1949, complaining of "one-child sterility." The only lesion discovered on examination was a cervical erosion, which was treated with the coagulating diathermy current. She was next seen during the tenth week of her second pregnancy, having been referred by her doctor because of excessive vomiting. During her first pregnancy she had required hospital treatment for hyperemesis gravidarum. The vomiting this time had started one week after the first missed period. At the beginning it had occurred two or three times daily, but had steadily become worse. Her doctor advised her on the general dietetic measures to be adopted and had tried the effect of insulin on four occasions. Despite this her condition deteriorated and eventually she was vomiting constantly by day and several times by night. During the eighth week of her pregnancy she was admitted to a Birmingham hospital as a case of hyperemesis gravidarum. She was treated for a period of 17 days along the usual lines, receiving phenobarbitone, vitamin B_1, intravenous glucose-saline, and glucose by mouth. There was some improvement in her condition with these measures, but nevertheless she was not cured completely of her vomiting and still had intense nausea when she left hospital. Her condition had been ascribed to neurosis.

Within three days of her discharge from hospital her condition relapsed and she was then admitted to St. Chad's Hospital for further treatment. Her general condition was poor and the acetone series was present in the urine in large amounts. A light diet with an abundant glucose and fluid intake was prescribed and steps were taken to rule out an associated cause of her vomiting. She was also given antihistamine drugs in the following regimen:

First Day.—Phenergan, one tablet at 6 a.m. and 10 p.m.; anthisan, one tablet at 10 a.m., 2 p.m., and 6 p.m.

Second Day.—Phenergan, one tablet at 6 a.m., 4 p.m., and 10 p.m.; anthisan, one tablet at 10 a.m., 1 p.m., and 8 p.m.

Fifth Day.—Phenergan, one tablet at 6 a.m., 12 noon, 5 p.m., and 10 p.m.; anthisan, one tablet at 10 a.m., 2 p.m., and 8 p.m.

Tenth Day.—Phenergan, two tablets at 6 a.m. and 10 p.m., and one tablet at 12 noon, 4 p.m., and 7 p.m.

The drugs were given in this manner in an effort to avoid, if possible, any feeling of drowsiness and also to make use of the minimum efficient dosage. It was found necessary to prescribe 5 mg. of amphetamine sulphate each morning when the dosage reached seven phenergan tablets per day; this counteracted the drowsiness very effectively.

By the end of the third day of treatment her condition had improved considerably, and by the fifth day all vomiting had ceased. The nausea gradually decreased and finally disappeared completely by the eighth day. She remained absolutely symptom-free until she was discharged from hospital on the nineteenth day, looking and feeling a "different woman." Thereafter the dosage was gradually decreased until a maintenance dose of three tablets a day was reached. This was discontinued after a period of three weeks; the symptoms did not recur, and at the time of writing this patient is approaching the end of her second trimester of pregnancy.

Commentary

The treatment of nausea and vomiting of pregnancy still constitutes a major problem in antenatal care. It is well recognized that spontaneous relief of symptoms may be expected by the end of the first trimester of pregnancy, and the majority of patients resign themselves to awaiting this happy outcome. Most cases, fortunately, are of mild degree and do not appear to require any special treatment. When treatment is necessary simple dietary measures usually suffice to give adequate relief. In many cases, however, despite such treatment, the annoying symptoms persist and render life miserable even if they do not constitute a potential danger to it. Such being the case, there is a need for a simple and safe method of treatment which will relieve the symptoms in those patients who do not find dietary measures sufficient.

The results of the investigation into the use of anthisan and phenergan in this condition suggest that the antihistamine drugs may offer just such a form of therapy. The majority of patients who received treatment with these drugs had already been treated along the usual lines, and, even allowing for the fact that some of these patients could have expected eventual relief without further treatment, it is difficult not to be impressed with the results obtained. At any rate, the success of this method has made it desirable to carry the investigation further with a series of patients treated in various other ways.

I am indebted to Messrs. May and Baker, Ltd., for supplies of anthisan and phenergan, and to the medical advisory staff of that firm for their advice and assistance.

ANAEMIA OF PREGNANCY IN GLASGOW AND DISTRICT

BY

J. M. SCOTT, M.D.
Assistant Pathologist

AND

A. D. T. GOVAN, M.B., Ch.B., F.R.F.P.S.
Director of Research, Glasgow Royal Maternity and Women's Hospital

The importance of anaemia as a complication of pregnancy seems to have diminished in recent years in many parts of the British Isles. For instance, Fullerton, Mair, and Unsworth (1944) found that in Aberdeen only 3.9% of pregnant women of the hospital class suffered from anaemia, and comparison with previous surveys in that area indicates a rapid diminution in the number of cases since 1935 (Davidson, Fullerton, and Campbell, 1935). Similar observations have been made in Edinburgh (Davidson, Donaldson, Dyar, Lindsay, and McSorley, 1942; Davidson, Donaldson, Lindsay, and Roscoe, 1944).

It is therefore surprising to find that in Glasgow anaemia is one of the commonest complications of pregnancy and among the most serious. Unfortunately no previous investigation has been made in this area, and it is therefore impossible to assess progress.

The following attempt to survey the present position on Clydeside and to discover the cause of this high incidence of anaemia is based on the investigation of 4,595 patients at the antenatal clinic of the Glasgow Royal Maternity and Women's Hospital during 1947 and the latter half of 1946.

Methods

These were the standard procedures adopted by most haematological departments. Venous blood, withdrawn without constriction, was collected in heparinized tubes from every patient attending the antenatal clinic, and all investigations were carried out within six hours. Haemoglobin estimations were made by the Sahli method, 65% on this scale being equivalent to 70% Haldane, or 10.36 g.%. The haemoglobinometers were standardized at regular intervals against blood of known oxygen capacity. Pipettes requiring no correction factor were used.

Most authors consider 70% Haldane to be the lowest normal value during pregnancy. Roscoe and Donaldson (1946) have suggested that this lower limit varies with the patient's age, and that pregnant women in younger age groups are in an anaemic state at haemoglobin levels which come within the range of normality for older women. In view of this we have classified our patients into three groups: those with haemoglobin readings falling within the range 60–65% Sahli were classified "low normals"; those with readings between 50 and 60% were considered moderately anaemic; and those with readings below 50% were regarded as severely anaemic.

Classification of Patients

We found that 17.6% of all patients were anaemic at their first visit to the antenatal clinic. In addition a further 2.5% seen early in pregnancy became anaemic at some later date in pregnancy. These latter patients were in the "low normal" group originally. This gives a high incidence of 20.1%. Owing to the natural curve of haemoglobin values occurring in pregnancy certain corrections

were necessary before we arrived at this figure: these will be discussed later. The majority were cases of moderate anaemia, but approximately 5% of all patients had a severe anaemia with haemoglobin readings below 50% Sahli (8 g.%).

Since the numbers were so great and the majority of patients appeared at the clinic for the first time just before term it was impossible to investigate each case fully. Accordingly 140 were chosen for investigation in some detail over an average period of 2.2 months, and in no case less than one month. The average duration of pregnancy at first attendance was 5.6 months, with a range of from three to eight months. All anaemic patients were treated empirically with iron, and according to their response to that treatment these 140 patients were eventually classified into three groups: (A) 112 (80%) patients who showed satisfactory progress; (B) 26 (18.6%) patients who maintained their original haemoglobin level but failed to improve; and (C) two (1.4%) patients who deteriorated.

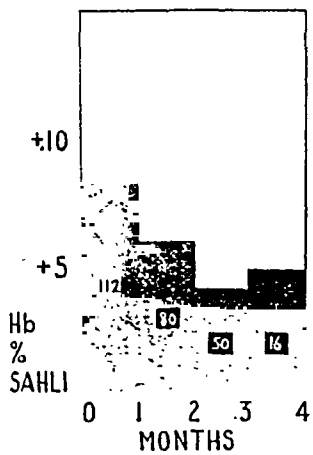

FIG. 1.—Whole of Group A. Monthly haemoglobin increments of 112 cases treated with iron as out-patients.

Group A

The results of treatment in this group are shown in Fig. 1. It will be seen that the increase in haemoglobin was greatest in the first month of treatment, and that the rate of increase diminished slightly in succeeding months. Seventy-seven of these patients were only moderately anaemic, and a graph of their monthly increments (Fig. 2) shows practically no curve. On the other hand, the remaining 35 severely anaemic patients showed a very steep curve of haemoglobin increments (Fig. 3), a rise of 10.8% being recorded in the first month, 5.4% in the second month, and 3.8% during the third month. Both curves (Figs. 2 and 3) are atypical when compared with non-pregnant cases, in which the rate of haemoglobin regeneration is said to be inversely proportional to the haemoglobin level (Whitby and Britton, 1946).

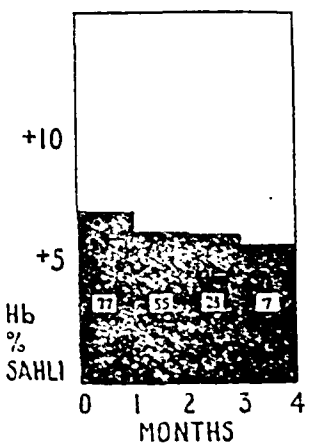

FIG. 2.—Cases of moderate anaemia in Group A. Monthly haemoglobin increments of 77 cases treated with iron as out-patients.

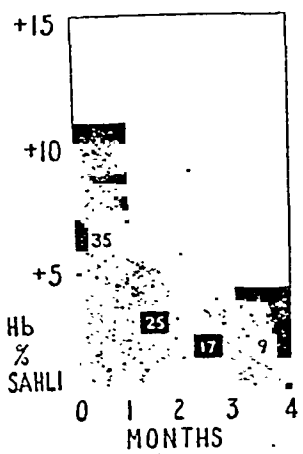

FIG. 3.—Cases of severe anaemia in Group A. Monthly haemoglobin increments of 35 cases treated with iron as out-patients.

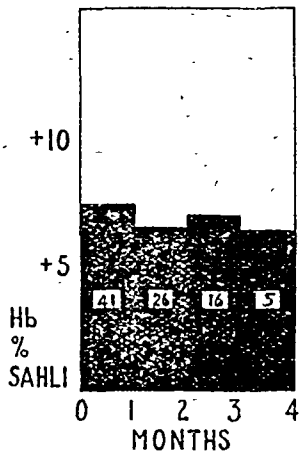

FIG. 4.—Cases of moderate "pure" anaemia in Group A. Monthly haemoglobin increments of 41 cases treated with iron as out-patients.

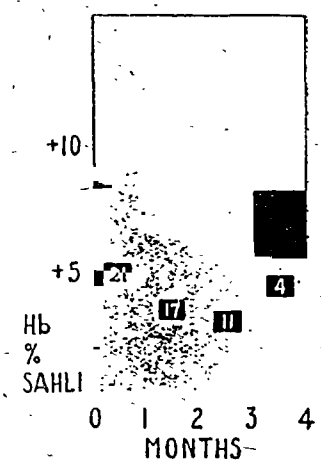

FIG. 5.—Cases of severe "pure" anaemia in Group A. Monthly haemoglobin increments of 21 cases treated with iron as out-patients.

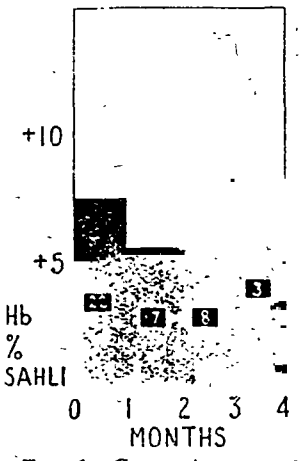

FIG. 6.—Group A cases of moderate anaemia with gastro-intestinal upset. Monthly haemoglobin increments of 22 cases treated with iron as out-patients.

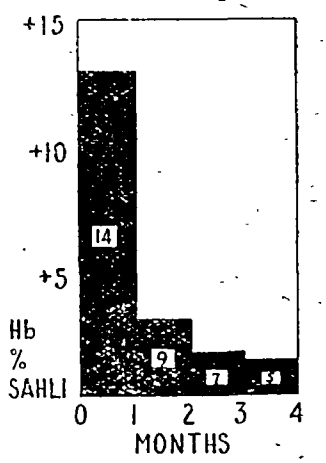

FIG. 7.—Cases of severe anaemia with gastro-intestinal upset. Monthly haemoglobin increments of 14 cases in Group A treated with iron as out-patients.

A further subdivision of these cases could be made on clinical grounds. Of the total, 62 were cases of "pure" anaemia—i.e., no other complication existed. Forty-one of these were of moderate degree, and their response is shown in Fig. 4; it was almost the same as in Fig. 2. The remaining 21 were cases of severe anaemia (Fig. 5), and these showed monthly increases which were inversely proportional to the haemoglobin level. In other words, the response of pregnant patients with uncomplicated severe iron-deficiency anaemia is the same as that shown by anaemic non-pregnant patients.

Of the remaining 50, 36 had a mild gastro-intestinal disorder: 22 of these were cases of moderate anaemia, and the curve of haemoglobin increments was similar to that of all moderate anaemias (Fig. 6); 14 were severely anaemic, the curve in their case being very steep (Fig. 7). A rise of 12.9% was recorded in the first month, but thereafter the response was only slight. It would therefore seem that a mild gastro-intestinal disturbance has little effect on the course of a moderate anaemia, but that in severe anaemia it seriously interferes with the response to treatment. *Since the initial response in these cases was satisfactory it is unlikely that the gastro-intestinal disturbance*

produced its effect directly by interfering with the absorption of iron. It is possible that it interfered with the utilization of iron, or it may have produced deficiencies of other haematinic factors.

The remaining 14 patients suffered from mild infections or high blood pressure, but the numbers in each group were too small to allow any further subdivision. The response to treatment did not appear to be affected. Most were cases of moderate anaemia.

While assessing the response to treatment of these 112 patients who improved it was noted that 20 showed a delayed response to iron. During the first month the increase was less than 5%. Thereafter the response was satisfactory (Fig. 8). The incidence of gastro-intestinal disorders and infections and the average duration of pregnancy were the same in this group as for the whole series. Neither these factors nor the severity of the anaemia could account for the delayed response. It is interesting to note that the response to iron therapy in this particular group of 20 patients is exactly the reverse of that seen in non-pregnant cases of anaemia. The importance of this group lies in the fact that no anaemia can be considered refractory to iron therapy unless treatment has been continued for more than one month.

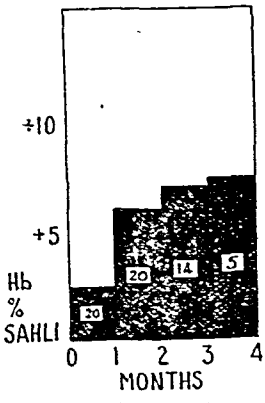

FIG. 8.—Monthly haemoglobin increments of 20 out-patients in Group A who showed a delayed response to iron therapy.

Group B

Although at first sight all of these 26 cases might be considered refractory, closer investigation suggests possible reasons for this apparent refractoriness in some. Thirteen of these patients received iron therapy for just over one month, and in view of the delayed response noted above it is not justifiable to consider them resistant to treatment. Two others developed severe infections necessitating confinement to bed for several weeks—an ample cause for their resistance (Pepper, 1927; Wintrobe, 1942; Saifi and Vaughan, 1944; Cartwright *et al.*, 1946). Another four were uncooperative, one patient improving after admission to hospital. Two patients had initial haemoglobin values of 55 and 57%. Although neither showed an increase of more than 5% in two months this was sufficient to bring them into the low normal range, and they might be incapable of further response. Only the remaining five cases of this group could be definitely regarded as resistant.

Group C

Of the two patients who deteriorated, one developed diarrhoea and vomiting in the ninth month, deteriorating thereafter. The other patient received iron for two months, during which time the haemoglobin fell 8%. She was admitted to hospital one week before term and given iron in large doses, but failed to respond although the blood picture was microcytic and hypochromic.

The first patient can scarcely be considered resistant to treatment in view of the complicating intestinal disorder. Out of the total of 140 cases of anaemia, therefore, six were definitely resistant.

Discussion

Although the survey covers a period in which many economical and social changes occurred it will be seen from Table I that there were only slight variations in the incidence of anaemia during 1946 and 1947. One out of every 20 to 25 patients attending the clinic was severely anaemic. It is interesting to note, however, that the average monthly haemoglobin readings for each of these years showed a tendency to rise in summer and fall in winter, but no correlation could be found between the incidence of severe anaemia and this seasonal variation. With the exception of a temporary rise during the Christmas season, when the numbers attending the clinic fell, this variation was quite regular, and it was also interesting to note that whereas the peak haemoglobin reading was in August, 1946, it was again reached in May, 1947, and fell rapidly thereafter.

TABLE I.—*Incidence of Anaemia*

Year	Severe Anaemias	Moderate Anaemias	Low Normals	Normals
1946	4%	17%	29%	50%
1947	4·8%	17·8%	24·5%	52·9%

From Table II it seems that age is significant only in severe anaemia. Parity is of no apparent importance.

TABLE II.—*Effect of Age and Parity*

	Age in Years	Standard Deviation	Parity	Standard Deviation
Normals	26·8	3·237	2·1	1·693
Moderate	28·3		3·5	
Average severe ..	30·7	2·812	3·6	2·810

Low Normal Series

In an attempt to elucidate the aetiology of anaemia of pregnancy a study of 85 patients whose haemoglobin values fell within the range of 60–65% was undertaken. These were followed from the fifth month of pregnancy onwards. They formed three groups.

Group I consisted of 44 patients who maintained their haemoglobin level throughout, sometimes increasing it towards term.

Group II consisted of 16 patients who showed an initial fall in haemoglobin but later improved. In none of these was the fall below 58%, and they could not be considered anaemic. Similar monthly variations in the haemoglobin values of normal patients have been noted by many authors (Meyer-Wedell, 1943; Roscoe and Donaldson, 1946; Kühnel, 1927; McGeorge, 1935; Boycott, 1936; Oberst and Plass, 1936; Thomson, Hirsheimer, Gibson, and Evans, 1938; Dieckmann, 1933). The maximum fall recorded in these patients was 4%, and these variations provide criteria for estimating the progress of any particular patient. It follows that in any patient of the "low normal" group a fall of less than 5% at any subsequent examination should not be considered significant. Doubt may be felt about the justification for this statement, since the original haemoglobin levels varied from patient to patient, and the stage of pregnancy on their first appearance at the antenatal clinic varied similarly. Statistical examination, however, showed that neither of these factors affected the validity of this conclusion.

Group III consisted of 25 patients who became anaemic. Incidentally, it was found in this group that if the haemoglobin fell below 58% Sahli the fall was progressive thereafter. Treatment was withheld until the haemoglobin fell below 55%.

A study of these three groups established certain facts relating to the onset of anaemia. Age and parity were of no significance. No difference in regard to these factors could be detected between those who maintained their haemoglobin level and those who became anaemic. Also,

since only a small percentage of "low normals" in any age group developed anaemia, pregnancy itself is not a cause of anaemia. Anaemia usually appears during the latter part of pregnancy, when foetal storage of iron is greatest. Maternal storage, however, is highest in early pregnancy, and it follows that anaemia of the later months may be related to the state of health earlier in pregnancy.

Investigation showed that 48% (12 cases) of those who became anaemic suffered from a gastro-intestinal upset in the early months, compared with 33% of those who maintained their haemoglobin level. Further, these 12 cases developed anaemia at the seventh month, whereas the remaining 13 with no such history did not become anaemic until the eighth month. Two conclusions may therefore be drawn. First, mild disorders of this nature in the early months are not a cause of anaemia later in pregnancy, although they probably hasten the onset. Secondly, the fact that the majority of those who deteriorated were healthy during the earlier months suggests that there was a relative deficiency of iron or other factors before pregnancy.

In order to test this hypothesis small groups of "low normal" patients were given dietary supplements. Twenty-five patients five months pregnant were given iron for several months. Twenty-five others received vitamin C, 150 mg. daily for one month, then 50 mg. daily till term. A similar group were given dietary advice on the type of food they should take and the best methods of preparing it. In addition, most received ½ lb. (227 g.) of liver each week for a period of not less than one month. Finally, one group received 3 dr. (11.6 g.) of "marmite" daily for one month. By that time most of them complained of nausea. All patients who deteriorated were given iron. The results of the test are shown in Table III, the control

TABLE III.—*Results of Therapy in the Low Normal Group*

Group	Improved	No Change	Deteriorated	Av. Rise in Hb After 1 Month of Iron Therapy
Control	4·7%	65·9%	29·4%	6·3%
Iron ..	40%	52%	8%	—
Vitamin C ..	16%	72%	12%	9%
Diet	32%	52%	16%	13%
Marmite	—	80%	20%	11%

group of 85 patients being used as a standard for comparison. From this it will be seen that iron therapy produced the best results but did not prevent the onset of anaemia in all cases. Vitamin C maintained the existing level of haemoglobin in a greater number of cases but was not so effective as iron in preventing deterioration. Its value may lie in its reducing power, thus improving the absorption of iron (McFarlane, 1936; Powell, 1944). Patients receiving special diet or marmite showed an increase in the incidence of deterioration, although not so high as in the control group. It is interesting to note the response to iron therapy of those who deteriorated in these groups. The steep rise in haemoglobin in those who had previously received special diet or marmite suggests that the rate of haemoglobin regeneration was enhanced by the diet, and that a small number of these patients had a deficiency of haematinic factors other than iron.

Summary and Conclusions

The results of the present survey show a high incidence of anaemia—namely, 17.6%—in pregnant women at their first attendance at the antenatal clinic of the Glasgow Royal Maternity and Women's Hospital. Reference to the group of low normals, however, shows that 29·4% of these patients ultimately become anaemic and a further 18.8% had readings below 60% Sahli at one time during pregnancy, though they did not develop anaemia. It is obvious that of the women attending the clinic those with haemoglobin readings below 60% at their first visit, diagnosed as anaemia, will not include the 29.4% of low normals who ultimately become anaemic, but may include the 18.8% whose haemoglobin reading is temporarily diminished. Correction for these figures gives an amended incidence of 20.1%—i.e., 20.1% of all patients seen for the first time at the clinic are or will become anaemic.

Direct comparison with other reports is difficult, but it is interesting to note that repeat surveys in other parts of Scotland show a diminished incidence of anaemia in patients attending antenatal clinics.

The reason for this high incidence on Clydeside is not apparent. The greatest emphasis has hitherto been laid on dietary iron intake. Coons (1932) estimated the daily iron requirements of the pregnant woman as 14.7 mg. Ohlson and Daum (1935) and the National Research Council, U.S.A. (1947), agree with his figure. McCance and Widdowson (1946), however, put the level as high as 20 mg. per day. Diet in the British Isles has become fairly standardized in recent years and it is therefore difficult to understand why anaemia of pregnancy should be so common in Glasgow. We have recently undertaken a dietary survey of cases of anaemia, and although to date we have examined only 16 patients the results emphasize the problem. The average daily iron intake of these patients was 16.67 mg., which is above the standard in America. It seems likely that social habits and environment may prove more important than iron intake as factors inducing anaemia in the pregnant woman.

Several points arise out of the investigation of cases of anaemia and of patients with "low normal" readings. These are best summarized as follows :

1. Thirty per cent. of all women with haemoglobin readings in the range 60–65% Sahli become anaemic if untreated.

2. Iron is the best form of preventive therapy, but an adequate intake of vitamins B and C should be maintained.

3. In these patients 58% Sahli (9.28 g. %) seems to be a critical level. Below this figure progressive anaemia develops.

4. In estimating progress a fall of less than 5% is not significant in any individual patient.

5. Pregnancy is not a cause of anaemia, and age and parity play no part in its onset.

6. Mild gastro-intestinal disorders in the early months hasten the onset of anaemia but are not responsible for it.

7. Those patients who develop anaemia are probably cases of deficient iron storage, and the defect arises before pregnancy.

8. In established cases of uncomplicated severe anaemia the response to iron therapy is similar to that obtained in non-pregnant cases. Moderate anaemias show a regular response which does not vary with the haemoglobin level.

9. When the anaemia is complicated by a gastro-intestinal disturbance there is no difference in response to treatment provided the anaemia is of moderate degree. When the anaemia is severe the response, initially good, practically ceases.

10. In 17.8% of cases the response to iron by mouth may be delayed for as long as one month.

11. An unsatisfactory response was obtained in 20% of cases, but reasons for this could be found in all but six cases, or 4.5%.

ACUTE MASTOIDITIS IN CHILDREN TREATED WITH PENICILLIN AND SULPHADIAZINE

BY

A. J. MOFFETT, F.R.C.S.
Surgeon

AND

G. A. DALTON, M.B., D.L.O.
Junior Registrar

Ear, Nose, and Throat Department, United Birmingham Hospitals

It has been said that penicillin places a premium on good surgery, but is no substitute for it. While not preparing to dispute the former, the series of 17 cases recorded below would largely appear to disprove the latter.

It has been the practice at one ear-and-throat clinic at the Children's Hospital to treat as out-patients large numbers of cases of mastoiditis, early or subacute, by the extensive use of the sulphonamides and penicillin in the form of an oil emulsion, reserving for admission those cases which hitherto had appeared to demand immediate operation. While the possible risks attached to this procedure laid it open to criticism, the difficulties of obtaining adequate facilities for in-patient treatment within this or any other hospital in the vicinity were so great that it was considered a justifiable expedient.

The results, however, were so satisfactory that it was resolved to apply this method of treatment to those cases of mastoiditis which by all previous standards demanded immediate operation. The cases in this series, seen within a period of three months, are consecutive ones in which there could be no shadow of doubt of a clinical diagnosis of acute mastoiditis, and were treated by conservative methods. Cases were selected on admission and none was excluded on the grounds of its severity. Only those in which the disease had progressed so far as to produce, in addition to systemic disturbances, tenderness, swelling, oedema, and in some cases a fluctuating abscess over the mastoid process were included in the series. All showed, to a greater or lesser degree, the typical forwards and downwards displacement of the ear so well shown in the accompanying photographs. This, coupled with the appearance of the drum and meatus, left no doubt of the diagnosis nor, by the usual standards, of the necessity for operation. *X*-ray examinations were made only in the later cases in the series, and bacteriological examinations not at all. The latter is unfortunate, because it may be that the prevalent invading organisms at the time the cases were admitted were particularly penicillin- or sulphonamide-sensitive. All cases originally selected are recorded. A careful watch was kept throughout for signs of intracranial complications, but none occurred.

Treatment

On admission to hospital the following routine treatment was adopted: *Myringotomy* was performed in those cases in which the drum was intact and distended. *Intramuscular penicillin* was given in watery solution, 50,000 units six-hourly, in most cases. In the more severe cases 100,000 units were given six-hourly, and in one case 50,000 units three-hourly. *Sulphonamides* were given either four- or six-hourly, according to convenience in dosage, up to a total dose varying from 10 g. in infants to 30 g. in children of 10 years and over. No sulphonamide was given in one case in which there was acute glomerulonephritis. Sulphadiazine was used in most cases; and mist. sulphonamide co. (consisting of sulphadiazine 37%, sulphathiazole 37%, and sulphamerazine 26%) in younger children. Great attention was paid to a large fluid intake.

Local treatment consisted in careful cleaning of the meatus thrice daily and instillation of penicillin aural drops, 10,000 units per ml. As most of the children were drawn from the working-class districts of the city, one of the most important factors in the recovery of these cases was undoubtedly the excellent nursing care and attention to general health which they received.

The following is a summary of the notes of one of the most striking cases.

Case 1

Admitted April 13, 1948, aged 4 years, under the care of one of us (A. J. M.). Five weeks previously this child developed measles with otalgia and bilateral otorrhoea. The left otorrhoea ceased four weeks later, but the right otorrhoea had continued and right otalgia had been severe for the last three days. A right post-aural swelling was noticed three days before admission. It had since become worse.

FIG. 1.—Photograph of Case 1 taken on admission.

On examination the child looked pale and ill. Temperature 100° F. (37.8° C.). From the right ear came a profuse muco-purulent discharge, the exact source of which was obscured by deep meatal oedema. There was considerable diffuse periostitis over the mastoid process, which was extremely tender. The pinna was pushed down, forwards, and outwards (see Fig. 1). The left drum was wrinkled but without active inflammation. Treatment consisted of systemic penicillin, mist. sulphonamide co., and penicillin aural drops.

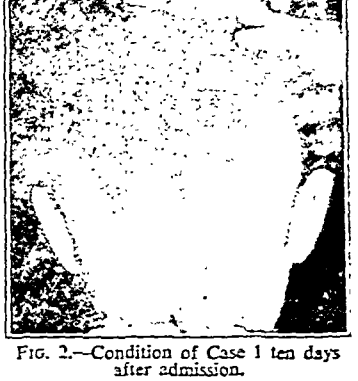

FIG. 2.—Condition of Case 1 ten days after admission.

Details of Remaining Cases

Case	Age	Duration of Symptoms	Physical Signs	Progress	Duration as In-patient	Follow-up
2	7 years	2 weeks	Right mastoid tenderness. Periostitis, especially over lateral sinus. Profuse discharge from posterior perforation	3 days after admission: otorrhoea ceased. 8 days: periostitis gone. 12 days: drum scarred; not inflamed	12 days	3 weeks after discharge: no complaints. Drum scarred; otherwise normal. Mastoid process normal. Hearing excellent. Circularized after 11 months: no further ear trouble
3	6 years	5 days	Right ear: swelling over Macewen's triangle and down post-aural groove. Copious pulsatile serous discharge from myringotomy (performed day before admission). Hearing: whispered voice at right ear	4 days after admission: otorrhoea ceased. 5 days: periostitis gone. 7 days: drum normal. Hearing: whispered voice from 5 ft. (1·5 m.) distance	7 days	6 weeks after discharge: no complaints. Right drum slightly retracted. Freely mobile. Hearing: W.V., right 10 ft. (3 m.), left 12 ft. (3·66 m.). Circularized after 9 months: no further ear trouble
4	19 months	3–4 weeks	Right ear: large post-aural swelling, pushing pinna down and out. Thick creamy discharge from posterior perforation in drum. Drum deeply injected	3 days after admission: swelling smaller but fluctuant. 8 days: swelling gone; otorrhoea ceased. 11 days: perforation healed	11 days	2 weeks after discharge: no complaints. General condition excellent. Mastoid process normal. Drum thickened but flat and white. Circularized after 10 months: no ear trouble of any sort
5	2 months	1 day	Left pinna pushed downwards and forwards by periauricular oedema. Meatus oedematous. Purulent discharge	3 days after admission: condition unchanged. 4 days: mastoidectomy decided on for next day unless much improved. 5 days: discharge ceased; meatal oedema subsiding. 11 days: postauricular and meatal swelling gone. Drum injected. 19 days: ear appears normal in all respects	19 days	10 weeks after discharge: "perfectly healthy baby"; taking feeds and sleeping well; mastoid process and zygoma normal; drum grey and normal in every respect. Circularized after 12 months: no ear trouble of any sort
6	7 years	5 days	Left drum bulging. Mastoid tenderness. Periostitis over Macewen's triangle and mastoid tip	On admission: myringotomy performed. 2 days after admission: tenderness gone. 4 days: otorrhoea ceased; swelling gone. 8 days: drum quite normal	12 days	9 weeks after discharge: "no complaints whatsoever"; mastoid processes normal; both drums quite normal and mobile. Hearing: whispered voice—right and left, 14 ft. (4·26 m.). Circularized after 11 months: had one attack of right otalgia; no trouble with left ear
7	5½ years	2 weeks	Right pinna displaced down and out. Mastoid process red and tender. Deep meatal oedema. Purulent otorrhoea	7 days after admission: periosteal thickening gone. 9 days: otorrhoea ceased. 12 days: drum thickened; otherwise normal	12 days	6 weeks after discharge: "no complaints at all. Better in every way"; mastoid process normal; drum retracted and poorly mobile; malleus prominent. Hearing: W.V. right 10 ft. (3 m.), left 12ft. (3·6 m.). Circularized after 8 months: no ear trouble
8	6 years	5 weeks	Left ear: profuse muco-purulent discharge. Periostitis over Macewen's triangle. Drum not seen owing to difficulty in examining child	6 days after admission: periostitis gone. 7 days: otorrhoea ceased. 8 days: drum white and flat	8 days	7 weeks after discharge—both drums quite normal and mobile. Mastoid processes normal. Hearing: W.V. right 12 ft. (3·6 m.); left 14 ft. (4·26 m.). Circularized after 11 months: no ear trouble of any sort
9	2½ years	4–5 weeks	Right ear: profuse purulent discharge from antero-inferior perforation. Drum deeply injected. Severe periostitis over whole of mastoid process extending above pinna along zygomatic root. No fluctuation	2 days after admission: swelling gone except for small area of thickening over centre of mastoid process. 4 days: otorrhoea ceased. 5 days: perforation healed. 9 days: mastoid process clinically normal	9 days	Circularized after 10 months: no further ear trouble
10	3½ years	1 month	Right otalgia for one month and right otorrhoea for one week. Post-aural swelling for one day. Continuous haematuria for one week. Right ear: large discoloured swelling over mastoid process, with fluctuation, maximal over Macewen's triangle; thick discharge from macerated drum. Urine: red cells and granular casts; albumin. Blood urea 31 mg./100 ml. Blood pressure 100/70. Abdomen: *nil* abnormal. Diagnosis: acute glomerular nephritis, complicating acute mastoiditis	3 days after admission: otorrhoea ceased. 5 days: swelling gone; meatus much less oedematous. Urine contains R.B.C.s and no casts. 11 days: meatus normal; drum scarred, otherwise appears normal	12 days	T. and A. 3 months later. Circularized after 10 months: no ear trouble since original attack; nephritis cleared up in 3 months
11	7 years	1 week	Previous history of severe right otalgia, 4 years and 18 months. Temperature 100·2° F. (37·9° C.). Right ear: meatal oedema, especially posteriorly; drum red and bulging; 3-point tenderness of mastoid, especially over tip	On admission: right paracentesis performed. 3 days after admission: tenderness gone. 5 days: incision healed. 7 days: drum scarred; otherwise normal	8 days	9 weeks after discharge: no complaint of ear at all; 2 head colds since discharge, but no otalgia. Right mastoid process feels normal; drum slightly retracted anteriorly, and scarred posteriorly by myringotom mobile. . left 12 ... months: no further ear trouble
12	3 years	3 weeks	Left ear: fluctuant tender swelling in post-aural groove; meatal wall sagging postero-superiorly; drum macerated (mostly obscured by meatal swelling). Radiograph: "infected left mastoid"	2 days after admission: swelling much smaller. 3 days: profuse left otorrhoea started. 9 days: mastoid process normal; attack of haematuria lasting a few hours; urine contained red cells but no other abnormality; sulphadiazine stopped. 10 days: otorrhoea ceased. 11 days: meatal swelling gone; drum landmarks visible	14 days	2½ months later: no further ear trouble; drums grey and retracted
13	4 years	4 weeks	Right ear: red tender swelling over Macewen's triangle; mastoid tip tender; deep meatus oedematous; drum obscured by hard wax. Radiograph: "infected right mastoid"	4 days after admission: swelling gone except for slight periostitis over upper part of mastoid process. 8 days: mastoid process normal. 10 days: meatus normal; still not possible to remove hard wax. 15 days: drum normal	15 days	Circularized after 10 months: child well; no ear trouble of any sort
14	12 years	3 weeks	History of 3 weeks' right otorrhoea following occasional otalgia for 6 months. Right ear: severe post-aural swelling. Radiograph: "infected right mastoid." Hears whispered voice at ear	4 days after admission: swelling gone; otorrhoea ceased. 8 days: drum normal; mastoid process normal; hears whispered voice from 6 ft. (1·8 m.) both sides	9 days	1 month: right ear: drum retracted; hears whispered voice at 5 ft. (1·5 m.) right, 8 ft. (2·4 m.) left

Details of Remaining Cases (continued)

Case	Age	Duration of Symptoms	Physical Signs	Progress	Duration as In-patient	Follow-up
15	4½ months	8 days	Right ear: swelling above and in front of pinna, pushing it down and out; no fluctuation; slight discharge from myringotomy incision, performed 2 days before admission. Radiograph: "A few infected zygomatic cells on the right side"	2 days after admission: otorrhoea ceased. 5 days: swelling gone; drum appears normal. 8 days: diarrhoea. 9 days: vomiting also. 10 days: temperature and pulse rates raised; right zygoma feels warmer, and is slightly reddened and more prominent than the opposite side; right cortical mastoidectomy performed; the major part of mastoid process normal, but a chain of infected zygomatic cells found. 12 days: general condition much improved. Steady uneventful recovery	29 days	[illegible] again 11 months
16	8 years	7 weeks	Left ear: tender over lateral sinus; drum bulging postero-superiorly; purulent discharge from antero-inferior perforation	2 days: tenderness gone. 3 days: otorrhoea ceased. 10 days: drum retracted. 11 days: home	11 days	Circularized after 9 months: no further ear trouble
17	6 years	2 weeks	Right ear: profuse purulent discharge from anterior perforation. Tender mastoid tip	2 days: tenderness gone. 11 days: otorrhoea ceased	13 days	Circularized after 10 months: one attack of acute R.O.M. 4 months after discharge. Cleared up in a few days on sulphonamide and penicillin drops, given in O.P.

Progress.—April 17: Right ear dry; perforation seen to be antero-inferior; no palpable periostitis now, but ear still lower than opposite side. April 19: Perforation healed. April 23: Pinna back *in normal position* (Fig. 2). *April 25: Could hear* the whispered voice at 15 ft. (4.57 m.) both sides. Right drum normal except for the antero-inferior scar. May 5: Transferred to convalescent home.

Subsequent History.—June 17: T. and A. July 15: Both ears dry; no ear trouble since May 3. Circularized after nine months (February, 1949): *No further ear trouble.*

The remaining cases are described above in tabular form.

Response to treatment was immediately noticeable in the general condition of the children. This in our opinion is the most important criterion of improvement in all acute mastoid cases. If the child looks as if it were making progress it is making progress, the constitutional condition reflecting the improvement in the ear. The slightly yellowish appearance of the complexion reminiscent of the tint of a telegram envelope, easy with practice to recognize but difficult to describe, rapidly gives way to a healthy pink. This alteration in appearance is often discernible within a few hours after treatment has begun, and precedes any obvious local change. The temperature and pulse rate fall rapidly at first and then move gradually to normal. Local changes in the ear quickly follow. The redness and tenderness rapidly disappear, the oedema subsides first, and is followed by the disappearance of fluctuation as the abscess, where the infection has burst through the bone, absorbs. The ear returns to its normal position, discharge ceases, the drum regains its colour and lustre, and hearing is restored. Many of these changes are accomplished in 48 hours, and are usually complete within a week.

We consider that the end-results of this method of treatment, as shown by examination or replies to questions several months afterwards, are at least as satisfactory as if the cases had been operated on; and that after such a lapse of time any further ear trouble is more likely to be a reinfection than a "lighting-up" of the old one, and would be equally likely to occur in children upon whom mastoidectomy had been performed.

Dr. T. M. Montford, M.O.H. of Castle Donington and deputy chairman of the Leicestershire and Rutland Executive Council, was re-elected a member of the Management Committee of the Association of Executive Councils (National Health Service) at the Annual Conference held at Bournemouth recently.

ELECTROCARDIOGRAPHIC INVESTIGATION OF 264 CASES OF HYPERTENSION

BY

POUL BECHGAARD, M.D.

(From the Medical Out-patient Department of the Rigshospital, Copenhagen (Professor Eggert Möller, M.D.))

Improvement in the electrocardiogram is an objective criterion to which the utmost importance has been attached in estimating the effect of treatment of essential hypertension. It has long been known that confinement to bed may in itself produce temporary improvement in the electrocardiogram. It is a matter of great interest that more comprehensive investigations carried out within recent years have revealed considerable and lasting improvement in the electrocardiograms of patients with hypertension, notably in the T-waves, as a result of dietetic treatment (Bryant and Blecha, 1947; Kempner, 1948; and others) and of sympathectomy (Canabal *et al.*, 1945; Peet and Isberg, 1946; Hammarström, 1947; and others).

There are few comparative records of electrocardiograms of untreated patients with hypertension followed up over a fairly long period. Canabal *et al.* (1945) recorded the electrocardiograms of 56 patients under 55 years of age through five years and found improvement in five cases only, all of them women under 50. They concluded that the electrocardiographic changes in hypertension tend to show that improvement occurs in few cases only, and then chiefly after acute conditions such as myocarditis and infarction. Rasmussen and Böe (1945), after six years' observation of 39 hypertensive patients, found that the electrocardiogram showed deterioration in 14 cases, while it was unchanged in 22 (of which 15 were normal) and improved in only three.

In a previous follow-up of 1,000 out-patients with hypertension (Bechgaard, 1946) with a blood pressure on the first examination of 160/100, or 180 mm. systolic or more, I had not given sufficient attention to the importance of this fact and had not followed the electrocardiograms of the individual patients with this in mind. The electrocardiograms have therefore since been revised. On the first examination 890 patients had been submitted to electrocardiography. As appears from Table I, and from a statement by Aastrup (1937), the prognosis was considerably

worse for patients with a morbid electrocardiogram on the first examination than for those with a normal one.

TABLE I

E.C.G. on First Examination	No. of Patients	Second Examination	
		Living	Dead
Normal	753	591	162
Morbid	137	54	83

Present Investigation

Of particular interest are the electrocardiograms of 264 hypertensive patients under the age of 60, all of whom were alive 11 years later and all belonging to an age at which sympathectomy may be considered. In all these cases electrocardiograms were taken at the beginning and the end of the observation period, and in several instances once or more within this period. Two-thirds of these patients were women.

The usual criteria of a myocardial lesion have been applied in interpreting the electrocardiograms. An electrocardiogram with an isolated left-axis deviation was regarded as normal. The T-waves were accurately measured. To record an improvement it was required that T1 and T2 should be at least 0.1 mV higher at the follow-up than on the first examination.

In 162 cases the electrocardiogram was normal both on the first and on the second examination; in 48 the electrocardiogram was normal on the first examination but at the follow-up showed marked deterioration, revealing signs of a myocardial lesion in all cases; and in 45 cases morbid electrocardiograms on the first examination were mainly unchanged or aggravated at the follow-up. As shown in Table II, in only nine cases had the electrocardiogram

TABLE II

	Cases
Normal E.C.G. on both examinations	162
Normal E.C.G.→ morbid on second examination	48
Morbid E.C.G. on both examinations	45
E.C.G. improved during the observation period	(9) 3
Electrocardiograms observed for from 4 to 11 years	264

improved in the course of the observation period. In three of these nine cases the T-wave in the first lead showed marked improvement, being at least 0.1 mV higher than on the first examination, and in two of them it had changed from negative to positive. In three cases a left-axis deviation had subsided, and in three some ventricular extrasystoles present on the first examination had disappeared.

It is only in the first three cases that we can say for certain that a really morbid electrocardiogram had undergone a change for the better. Hypertension persisted in all cases.

Discussion

The conclusion to be drawn from this investigation must therefore be exactly the same as that of Canabal *et al.*—namely, that definitely morbid electrocardiograms of patients with hypertension show very little tendency to improve when acute conditions, notably cardiac infarction, are left out of account, as in our cases. Improvement occurred in three patients only. This figure, though smaller, is in accord with the results of the investigations made by Canabal *et al.* and Rasmussen and Böe—particularly so when the longer observation periods of my investigations are taken into account.

Actually, these investigations give too optimistic a picture of the spontaneous improvement in the electrocardiograms, since patients who died within the observation period have not been included. The deaths among patients with a morbid electrocardiogram on the first examination were in the great majority of cases due to cardiac diseases. It is to be expected, therefore, that the proportion of spontaneous improvements would have been smaller if it had been possible to include these patients.

Lasting improvement in the electrocardiogram in hypertension, notably improvement of the T-waves, may therefore be regarded as a criterion of the efficacy of a treatment, spontaneous improvement being a comparatively rare occurrence. It may furthermore be remarked that in more than half of the patients the electrocardiogram remained normal throughout the observation period.

Great prognostic importance must also be attached to improvement in the electrocardiographic findings, since a morbid electrocardiogram must be regarded as an extremely grave prognostic sign in cases of essential hypertension. In my previous investigations into the prognosis of 1,000 hypertensive patients the mortality rates were compared with the average mortality among the Danish population, the age distribution and the length of the observation period being taken into consideration. For men with electrocardiographically demonstrable myocardial lesions the mortality was found to be 5½ times as high as the average mortality, and for women about 3 times as high, as compared with 2 and just over 1 respectively for hypertensive subjects with normal electrocardiograms.

Summary

The electrocardiograms of 264 out-patients under 60 years of age with essential hypertension have been followed for from 4 to 11 years.

Of these, 162 had normal electrocardiograms on both the first and the second examination.

Forty-five patients presented fairly unchanged morbid electrocardiograms on the two examinations.

In 48 cases a marked deterioration had occurred.

In nine cases the electrocardiogram had improved, but significantly so in three cases only.

The follow-up of 1,000 patients with hypertension disclosed a mortality rate for men with electrocardiographically demonstrable myocardial lesions 5½ times greater, and for women nearly 3 times greater, than the average mortality, against 2 and 1 respectively for hypertensive subjects without this sign.

A treatment of essential hypertension which is capable of effecting a regular and lasting improvement of the electrocardiogram must be regarded as of real value.

The Ministry of Health states that in the removal of persons of unsound mind to mental hospitals it may be necessary in some cases to have trained staff from the hospital in attendance to accompany the patient in the ambulance or car and if necessary to assist in the removal. Requests for assistance will usually be made by duly authorized officers of local health authorities, and when hospital management committees are asked to provide trained personnel for this purpose they should do their best to comply. The smooth working of arrangements will entail the closest co-operation between officers of the hospital management committee and of the local health authority. No charge will be made to local health authorities for the services of staff provided under these arrangements.

SENSITIZATION TO DENTURE MATERIAL AS A CAUSE OF ANGULAR STOMATITIS

BY

H. R. VICKERS, M.Sc., M.B., M.R.C.P.

Consultant Dermatologist, Rupert Hallam Department of Dermatology, Royal Infirmary, Sheffield

Cracking of the angles of the mouth may be due to many causes. These vary from mechanical maceration by dribbling resulting from ill-fitting dentures to direct infection with monilia, staphylococci, or streptococci, and to that arising in association with vitamin deficiency, particularly in ariboflavinosis. I wish to draw attention to a further cause which is not generally recognized—fissure formation due to stomatitis caused by sensitization to denture material. Of nine cases of denture stomatitis I have seen during the last four years, in seven I was consulted because of cracks at the angles of the mouth, and only after direct questioning did these patients mention painful gums. All seven cases had been treated by local applications and by various vitamins without success, some of them for several years.

Stomatitis arising from sensitization of the buccal mucous membrane to the material of which dentures are made has been recognized for many years. Prinz and Greenbaum (1939) state that "rubber sore mouth" has been known ever since Thomas W. Evans, of Paris, introduced in 1844–5 vulcanite as a base for the construction of artificial dentures. The condition is mentioned in many of the standard dermatological textbooks, such as those of Sutton and Sutton (1939), Becker and Obermayer (1940), and Andrews (1946). Lain (1932) discussed briefly the basic constituents of dental plates and stated that probably the substance mainly responsible for the stomatitis is vermilion (mercury sulphide), which, in plates that have not been sufficiently hardened, is easily liberated on to the mucous membranes. Lindsay (1928) described glossitis occurring in a patient who was shown to be sensitive to a "plastic" type of denture by patch testing. Rattner (1936) described three cases of stomatitis due to sensitization to the newer plastic materials—two of which gave positive patch tests to the dentures strapped on to the arm for 48 hours. In the third case the patch test on the arm was negative, but Goldman and Goldman (1944) have shown that it is necessary in some cases to perform the patch test on the mucous membrane to demonstrate sensitivity, and they have devised a technique for doing this.

The patch tests in the cases described below were performed by taking scrapings from the denture which was suspect and leaving these moistened scrapings in contact with the skin of the upper arm for 48 hours. There was no difficulty in reading the results. A more spectacular way is to strap the whole denture on to the skin, but my patients did not wish to be without their teeth for a period of two days.

In addition to the cracks at the corners of the mouth, the one feature common to all the patients was redness and engorgement of the whole of the mucous membrane which came into contact with the denture. The sharp line between the red inflamed denture-covered part of the hard palate and the adjoining normal uncovered part was most striking. In some cases the mucous membrane of the cheek was also affected, and one case had superficial glossitis of the part of the tongue in contact with the denture. All have been cured by changing their type of denture.

Case Reports

Case 1.—A woman aged 31, seen on January 15, 1945, complained of having had cracking at the angles of the mouth for the previous six years; this started about six months after wearing a new denture. She had failed to respond to many different preparations. There was no history of previous trouble and her general health was good. On examination the cracking of the angles of the mouth was severe and there was redness and swelling of all the mucous membrane which came into contact with her dentures. The line of demarcation on the hard palate between the engorged mucous membrane and the normal-looking posterior part of the palate was very well marked. There was no history of previous skin disease or of any relevant past illness. The dentures were made of red vulcanized rubber, and a patch test performed with scrapings was strongly positive, blisters being formed on the skin of the upper arm after contact with the scrapings for 48 hours. She was advised to stop wearing her dentures and to have a "plastic" denture after first being tested with the plastic material to be certain that she was not also sensitive to that. She was seen again on April 12, 1945, when she was completely cured. In a letter dated July. 30, 1949, she stated: "I have not had any recurrence of the trouble with my mouth and gums whatsoever."

Case 2.—A woman aged 46 was seen on January 7, 1946. She gave a history of cracking of the corners of the mouth for one month, and for a week before being seen she had mild dermatitis of the circumoral region, chin, and neck. She had worn "plastic" dentures for six years, and during this time often had ulcers of her gums. There was no previous history of skin disease. She had marked cracking of the angles of the mouth, with a dry scaling dermatitis of the circumoral region, the chin, and the anterior aspect of the neck. The mucous membrane in contact with the dentures was red and engorged, and showed the sharp line of demarcation described above. A patch test to the denture was strongly positive. She was advised to change to a vulcanite denture. On July 30, 1949, she wrote saying that she "had slight recurrence of the trouble about 12 months ago which quickly responded to treatment. Apart from this I have experienced no trouble whatsoever."

Case 3.—A woman aged 44 was seen on November 22, 1946. She had had cracks at the corners of the mouth for three years continuously in spite of various forms of treatment. She first had artificial teeth in 1938, and had since noticed soreness of her gums from time to time. On examination there were deep cracks at the corners of her mouth, and the mucous membrane showed the changes seen in the other patients. The dentures were made of red vulcanite, and a patch test was strongly positive. She was fitted with "plastic" dentures, and wrote in January, 1947: "I got my new plastic teeth on December 29, and am delighted to say the cracks in my lips have quite gone and my skin is clear. My mouth has lost its soreness and I am free from ulcers."

Case 4.—A woman aged 64 was seen on August 27, 1945. On January 1, 1945, she had an irritable rash on the central part of the face, involving the forehead, nose, mouth, chin, and neck. She also had noticed cracks at the angles of the mouth during this time. She had worn dentures for about 40 years. On examination she had dermatitis of the areas mentioned above, cracks at the corners of the mouth, and marked redness and swelling of the whole of the mucous membrane in contact with the dentures. The dentures were made of black vulcanite with red vulcanite at the gums. Patch tests to the black and red vulcanite, to lipstick, and to face powder were negative. The rash and cracking persisted in spite of treatment, and in April, 1946, she was asked to discontinue wearing her dentures. She left them out only at night, but even with this the condition improved. Eventually she was fitted with a plastic denture, and wrote to me on July 29, 1949, to say that she was perfectly well, with no trace of the trouble.

Case 5.—A man aged 74 had had cracks at the corners of the mouth for about four weeks when seen on October 12, 1948. He had worn dentures for about 30 years. In addition to the cracks there was redness and swelling of the buccal

mucous membrane. A patch test to dentures was strongly positive. He was fitted with "plastic" dentures, and when seen again on March 7, 1949, the cracks had gone and the stomatitis was cured.

Case 6.—A woman aged 39 came to the out-patient department on May 14, 1949, with an infected mole. Angular stomatitis had been present for five and a half years; she had worn vulcanite dentures for about six years, and examination revealed the characteristic redness of the denture-contact area. A patch test when first tried was negative, but when repeated a delayed positive result was obtained. She was fitted with new teeth and the cracks have now healed.

Case 7.—A woman aged 58, seen on July 30, 1949, had had cracks at the angles of the mouth for many years despite many different kinds of treatment. She has worn black vulcanite dentures for 35 years. The mucous membrane showed the characteristic appearance, and a patch test to the denture was strongly positive. She has now stopped wearing dentures and the condition is much better.

Comment

These cases establish the association between denture sensitization and angular stomatitis. It is of interest that all these patients were in the habit of keeping their artificial teeth in at night, and it is reasonable to postulate that such a practice leads more readily to the establishment of a contact sensitization. In view of the numbers of dentures worn this condition is relatively uncommon, but in all the above cases the gum sensitivity was discovered only by direct questioning and examination, so that probably many cases are missed.

ANALGESIA INHALER FOR TRICHLORETHYLENE

BY

H. G. EPSTEIN, Ph.D.

AND

R. R. MACINTOSH, D.M., D.A.

(From the Nuffield Department of Anaesthetics, University of Oxford)

Of the births in England and Wales 65% are supervised by midwives (Ministry of Health, 1946). In this circumstance the problem of the relief of pain is of lively interest to nearly half a million mothers a year, but is not easy of solution. The medical practitioner can choose the anaesthetic drug and vary its concentration to meet the requirements of any particular patient at any particular moment. The midwife, however, because of her limited training in anaesthesia, is at present restricted to apparatus set automatically to deliver 50% nitrous oxide and 50% air. This apparatus of Minnitt's (1938) has proved safe, but complaints are common that it is cumbersome, and in some hands the relief from pain it affords is disappointing. This may in some degree be attributable to the fact that the female is not mechanically minded, and gas-and-air apparatus does indeed need a modicum of attention from time to time. Whether more latitude should be allowed to midwives in the way of new apparatus and drugs is a serious question. Increased relief from pain is easily achieved by raising the percentage of any anaesthetic vapour inhaled, but, quite apart from any noxious effect this may have on the foetus, it carries with it the possibility that unconsciousness and its many attendant dangers may be produced in a susceptible patient; and it must be faced that the midwife is not adequately trained to meet such a situation. With this limitation in mind work is being carried out at various centres with the object of providing better relief of pain with apparatus as safe as Minnitt's, which has rendered such useful service for the past 15 years, but more portable and less likely to present technical difficulties to midwives.

There seems to be a widespread opinion that trichlorethylene is a good analgesic agent; when carefully given it affords very considerable relief of pain without markedly impairing consciousness. In 1943 Freedman introduced a small inhaler for trichlorethylene which, under certain conditions at any fixed ambient temperature, delivers a substantially constant concentration of vapour. This inhaler proved highly convenient and successful in some hands—so much so that on the recommendation of the Anaesthetics Committee of the Royal College of Obstetricians and Gynaecologists extensive clinical trials were carried out at various hospital centres to discover whether the apparatus was suitable for use by midwives in domiciliary practice (Royal College of Obstetricians and Gynaecologists Annual Report, 1947). As a result of these trials the committee reluctantly decided that the apparatus was not satisfactory, and this view was supported by laboratory tests which showed that, even if the apparatus is kept still, the concentration of vapour in the inspired air increases by 60% for a temperature rise from 20 to 30° C. Furthermore, marked fluctuations in concentration result from filling, shaking, or tilting the inhaler.

Constant Vapour Concentration

Before discussing the design of trichlorethylene inhalers delivering a substantially constant vapour concentration, the question naturally arises whether any fixed concentration of this drug in air would improve on the relief from pain afforded by the Minnitt gas–air apparatus and yet not be dangerous.

Special trichlorethylene inhalers in which the concentration could be varied at will in accurately known steps were handed over to our colleague Dr. E. H. Seward, and his observations (1949) suggest strongly that: (*a*) A trichlorethylene concentration of 0.5% v/v in air can be inhaled intermittently during labour over long periods. (*b*) After about three hours a slight cumulative effect may become noticeable in some patients. If in these cases the concentration is now reduced to 0.35% v/v this tendency is halted. (*c*) A very large proportion of patients prefer this method of pain relief to that afforded by gas and air.

In the design of apparatus to deliver a constant concentration of vapour of an anaesthetic liquid one of the main difficulties to be overcome is the effect of variation of vapour pressure with temperature. This can be obviated either by keeping the anaesthetic liquid in a thermostat, as for example in the Oxford vaporizer, or by introducing a compensating device which, for any rise in temperature, reduces the amount of vapour leaving the vaporizing chamber. The latter method was adopted by Goodman Levy (1905) in the design of his chloroform inhaler. During the last war this department was asked to produce a dosimetric chloroform inhaler for paratroops. The resultant

E.S.O. (Epstein–Suffolk–Oxford) apparatus also was based on the second method, and utilized a compensating device which reduces the amount of air drawn through the vaporizing chamber when the temperature of the liquid rises. This apparatus stood up to vigorous tests for robustness, and gave satisfactory results both in the laboratory and clinically. Many of the principles of the E.S.O. apparatus have been incorporated in the analgesia apparatus to be described.

A Hand-operated Inhaler

In our search for a constant-concentration inhaler for trichlorethylene analgesia various experimental models were constructed with devices—some hand-operated, others automatic—to keep the inhaled vapour concentration constant despite any changes in temperature of the liquid or the surroundings. Several of these models have given encouraging results in the labour wards of this hospital for the past year. An apparatus with an automatic temperature control has an obvious advantage, but a hand-operated control is more robust and foolproof, and we incline to the belief that it will be more satisfactory in the long run. On this account we confine ourselves at the moment to a consideration of a hand-operated model, a photograph of which is shown in Fig. 1; the diagram (Fig. 2) is intentionally schematic.

When the patient inspires, the non-return valve (NV) opens and air enters through a variable opening (a2) into the trichlorethylene chamber and emerges mixed with vapour; another current of room air is drawn through the permanently open by-pass of fixed size (a1) and dilutes the mixture issuing from the vaporizing chamber. If for a given size of inlet orifice (a2) and for a given temperature the concentration inspired by the patient is 0.5%, any change in temperature would alter this concentration. In order to maintain a constant concentration despite the change in temperature, compensation is effected by making the size of the air port (a2) variable. In the model illustrated the concentration can be kept constant over a temperature range from 12 to 37° C. (54 to 98° F.).

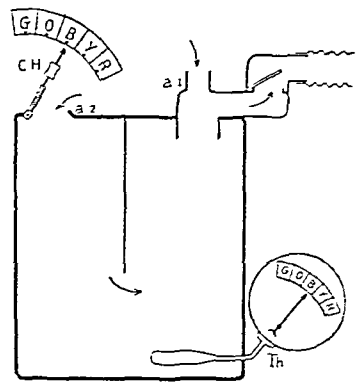

FIG. 2.—Schematic diagram of the apparatus.

On the dial of a metal thermometer (Th) are five equal sectors, each of a distinctive colour; the centres of these sectors correspond to the following temperatures: green 15° C., orange 20° C., blue 25° C., yellow 30° C., red 35° C. The movement of the compensator handle (CH) increases or diminishes the inlet (a2) to the vaporizing chamber, and the compensator handle can be set in any of five positions coloured to correspond with the colours on the five sectors on the thermometer dial (Th).

The apparatus is so constructed that the patient breathes 0.5% trichlorethylene vapour whenever the compensator handle is set to correspond to the sector which contains the thermometer pointer at that time. If, for example, the thermometer pointer lies within the blue sector, the compensator handle has to be set to the "B" mark. It is obvious that at high temperatures, when the thermometer registers in the red field and the compensator handle is set to "R," the inlet (a2) will be at its smallest; when the temperature is low enough to register in the green sector and CH is correspondingly set at "G," the opening (a2) will be maximal.

The heat capacity of the inhaler and heat transfer are such that the temperature of the anaesthetic liquid drops little during use in a room of reasonably constant temperature. If the temperature of the surroundings changes suddenly the internal temperature of the inhaler will follow, but only slowly. In practice, therefore, CH rarely needs to be reset. The statement that so long as CH is set to correspond to the colour indicated by the thermometer pointer the concentration of trichlorethylene vapour will be 0.5% needs but slight qualification. If the thermometer pointer is at the centre of a sector, say B, and CH is set to position B, the delivered concentration will in fact be 0.5%. If the pointer is in the right half of the sector, as shown in the diagram, the concentration will be slightly higher, and vice versa. If the pointer registers at the extreme right-hand side of a sector the concentration rises to 0.55%. However, we believe that in clinical practice such fluctuations of ± 10% in the vapour concentration are of little importance, and in speaking of "constant concentrations" possible variations within these limits are implied. It should be mentioned here that our analyses of vapour–air mixtures were carried out on samples of 2–3 litres.

The mechanism which permits delivery of a "weak" mixture (0.35%) instead of the "normal" concentration discussed so far is not shown in the diagram. It consists of a small disk which when rotated to the "weak" position opens a second air by-pass in addition to the permanent one (a1).

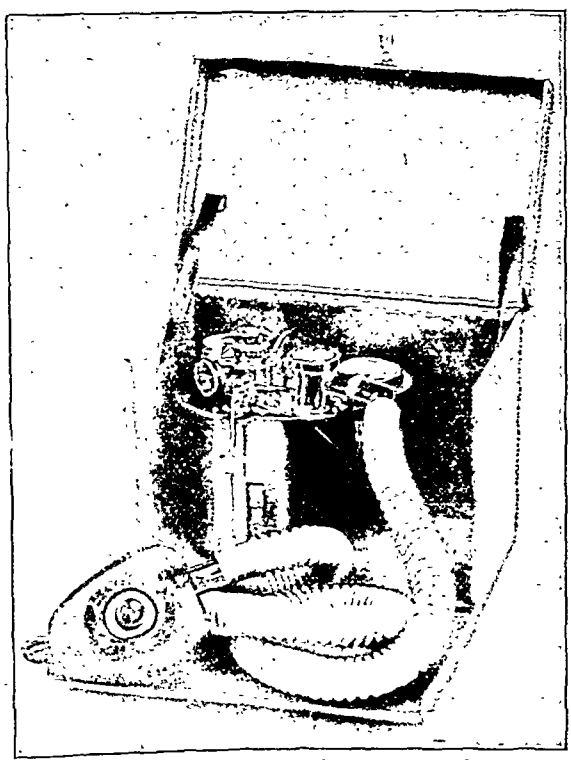

FIG. 1.—Photograph of a hand-operated model inhaler.

Besides changes in temperature other considerations must be borne in mind when designing an inhaler to deliver a fixed concentration of vapour. Unless care is taken, considerable fluctuations result from variation in the depth or rate of breathing. In the various models we have constructed the concentration remains practically constant for a range of respiratory volumes of from 6 to 15 litres per minute at rates from 12 to 30. Overfilling the vaporizing chamber with trichlorethylene is prevented by an overflow. Slow filling which occurs when the filler is at the low level of the overflow is avoided by placing the filler on top of the inhaler. Liquid does not spill to the outside during transport or if the inhaler should fall over. A glass level gauge permits an estimate of the consumption, and indicates by the "full" mark when no more liquid should be poured in. If this is overlooked the overflow comes into action almost at once. One filling is more than sufficient for a long case.

In view of the considerable cross-section of the vaporizer chamber, a special device is incorporated to give a reasonable movement of the level between "full" and "empty" corresponding to 1½ fl. oz. (42 ml.) of free liquid. The concentration of vapour remains constant whatever the position of the liquid level between the "full" and "empty" marks. Moreover, even if the level sinks out of sight, and the inhaler continues to be used, the concentration of vapour remains constant for at least three hours by virtue of trichlorethylene held in wicks. Despite the fact that the inhaler has a clearly visible liquid level—a not inconsiderable advantage—the concentration of vapour inhaled does not rise when the liquid has just been added to the inhaler, nor after the inhaler has been accidentally shaken, turned on its side, or completely inverted. These refinements would be futile if the permanent air inlet (a1) could be blocked, for the inhaler would then be dangerous in unskilled hands: accidental or intentional obstruction of this inlet has been made practically impossible. A feature of the apparatus is its low resistance to respiration compared with gas–air machines; inspiration is therefore more comfortable, and leaks due to an ill-fitting face-mask will be of less consequence in diluting the mixture reaching the patient. The apparatus is easily portable and weighs 11½ lb. (5 kg.) complete in its transit case, measuring 11 by 7 by 8 in. (27.5 by 17.5 by 20 cm.).

Some Practical Points

In using the inhaler care must be paid to three elementary points: (1) see that the liquid level lies between "empty" and "full"; (2) set the compensator handle to the colour indicated by the thermometer pointer; (3) if drowsiness or uncooperativeness should manifest itself the small disk previously referred to should be turned from "normal" to "weak," thus reducing the inhaled vapour concentration from 0.5 to 0.35% v/v.

It is unlikely that attention will have to be paid to any of these points during the course of an average labour. A very occasional glance at the thermometer pointer and control handle to confirm that the colours still coincide, and a look at the level gauge to see that it contains liquid, are all that is necessary. Movement of the non-return valve underneath its glass dome shows that the face mask fits reasonably well.

We are indebted to Imperial Chemical Industries Limited for a generous grant to meet laboratory expenses, and to our obstetrical colleagues in the United Oxford Hospitals for their willing co-operation. The apparatus in question can be obtained from the Medical and Industrial Equipment, Ltd., 12, New Cavendish Street, London, W.1, who contributed their usual enthusiasm and skill in production.

Medical Memorandum

Recovery from Botulism

Botulism is a rare condition in this country and has a very high mortality. All of the eight affected persons succumbed in the Loch Maree outbreak of 1922. The mortality is generally considered to be at least 50%.

CASE REPORT

A woman aged 33 had an evening meal of canned tongue shortly after Christmas, 1948. The tin appeared normal, and the contents, which received no further cooking, had no unusual taste. In the early hours of the next morning she awoke with severe headache and nausea, followed by profuse vomiting. In spite of feeling very ill, she got up and went for a drive with her husband. She continued to vomit intermittently throughout the day. On returning home she found that her face was crooked and drawn to the right side. The same night the vision in the left eye was misty and swallowing had become difficult; fluids were regurgitated through the nose. For the next few days she remained in bed with mild pyrexia up to 100° F. (37.8° C.) and continued to vomit. Constipation was severe. On getting up after ten days she noted some weakness of the left leg. The difficulty in swallowing and in using the left eye persisted.

I first saw the patient on February 19, 1949, seven weeks after the onset of symptoms. The condition had not been diagnosed at the onset and consequently no antitoxin had been administered. The following signs were present: moderate dilatation of the left pupil, which was active to light but inactive on accommodation and convergence; slight left-sided ptosis; and complete paralysis of the left masseter, temporal, and pterygoid muscles. There was no facial anaesthesia and the corneal reflex was present. The left facial muscles were completely paralysed, with the exception of the orbicularis oculi, in which there was a faint contraction. Taste was normal on the left, but there was hyperacusis in the left ear. Both sides of the palate were weak. Examination of the limbs showed no abnormality other than a moderate weakness of the dorsiflexors of the left foot. The superficial and deep reflexes were normal, and there was nowhere any change in cutaneous or deep sensation.

Twenty-four hours after eating the suspected meat the patient's daughter had an attack of vomiting which continued for two days. There was no involvement of the nervous system. The patient's husband, who also ate the same meal, was unaffected.

The history of gastro-intestinal symptoms occurring a few hours after the ingestion of tinned meat and followed by paralysis of cranial nerves some hours later is characteristic of affection by the toxin of *Clostridium botulinum*. The site of action of this toxin is uncertain, but its action is probably peripheral (on the motor-nerve endings in striated and non-striated muscles) rather than central, and this theory is borne out by the absence of reflex or sensory disturbance and the ultimate complete recovery in those patients who survive the initial acute phase (Dickson and Shevky, 1923; Cowdry and Nicholson, 1924).

Reviews

THE THYROID

Pathology and Surgery of Thyroid Disease. By Joseph L. De Courcy, M.D., and Cornelius B. De Courcy, M.D. (Pp. 476; illustrated. £2 10s.) Oxford: Blackwell Scientific Publications. 1949.

Two distinguished members of the clinic at Cincinatti, Ohio, which bears their name have added yet another to the long list of recent monographs on thyroid disease and surgery. It is in most respects a thorough survey of the subject, based on experience of some 15,000 thyroid operations done over a period of almost 30 years.

The authors express a number of more or less original opinions on various topics, and these must be heard with respect. They claim, for instance, to be the originators of the view that the beneficial action of Lugol's solution in the pre-operative treatment of toxic goitre is chiefly due to a mechanical effect; the rapid storage of colloid in the vesicles of the gland produces, they say, a temporary state of pressure within the gland with a consequent oedema and limitation of the blood supply. Within a short time the effect is lost because the circulation in the gland returns to normal with adjustment to the changed state. In their survey of the physiology and pathology of the thyroid the authors emphasize the part played by the reticulo-endothelial system of the liver in the regulation of the iodine content of the blood, and discuss the value of blood-iodine estimations in diagnosis and treatment. The value of thiouracil treatment is, of course, fully discussed, and like most other unbiased observers they conclude that the chief value of these compounds is in the pre-operative preparation of the patient. The possible uses of radio-iodine are also described, but its limitations and dangers seem at present, at the De Courcy Clinic, to outweigh its virtues. The use and control of this dangerous weapon are indeed still in an experimental stage.

The difficult question of the aetiology and relationship of the two conditions known as Riedel's thyroiditis and Hashimoto's disease is fully considered, and the authors are inclined to regard them as separate clinical entities. They advance the theory that Riedel's thyroiditis begins as an inflammation outside and around the gland—a peri-thyroiditis, with fibrosis spreading into the gland from the periphery. Although the process certainly seems to affect the surrounding tissues, this explanation is unlikely to satisfy pathologists. The origin of the peri-thyroiditis is in any case left unexplained.

In this comprehensive survey the technique of thyroid surgery is given a relatively small space. It is interesting to note that the authors do not ligate the inferior thyroid artery, because they believe that the procedure "entirely destroys the blood supply of the parathyroid bodies and encourages the development of tetany." This view is contrary to the experience of most thyroid surgeons, and it is surprising that the bogy should still have any influence. The "enucleation" of thyroid adenomas from within the gland is also a procedure usually regarded as long outmoded.

A curious defect in the book is the very perfunctory account of cardiac disease in relation to thyroid surgery. The use of quinidine in the post-operative treatment of auricular fibrillation appears to be unknown to the authors, and far greater reliance is placed on the use of digitalis than would seem to be warranted by recent experience in Great Britain. A most interesting view, however, is expressed concerning the administration of desiccated thyroid gland for at least three months after thyroidectomy for toxic goitre. The authors believe that this will almost invariably prevent any recurrence of hyperthyroidism by putting the remainder of the gland entirely at rest. They even describe the history of a patient with severe toxic goitre who was cured by the administration of dried thyroid tissue without any surgical treatment at all. This subject needs further investigation.

Though not without defects, the book is interesting to read and most suggestive to any thyroid surgeon who looks beyond the mere technique of his craft. It is fully supplied with references at the end of each section.

GEOFFREY KEYNES.

VISCERAL PAIN

The Mechanism of Abdominal Pain. By V. J. Kinsella, F.R.C.S., F.R.A.C.S. (Pp. 230. £1 12s. 6d.) Sydney: Australasian Medical Publishing Company. *1948.*

The author is a distinguished Sydney surgeon who for many years has devoted himself to a study of the problems of abdominal pain. He is scientifically minded, well informed, and a keen and painstaking observer; this review of his findings will be read with profit by both clinicians and physiologists. Mr. Kinsella might well have given additional space to a more detailed account of his original observations and less to a consideration of the views of the classical writers like Ross, Lennander, Head, Wilms, Mackenzie, and the rest, whose theories and concepts have in the main outlived their usefulness and now tend to cripple fresh thinking on the subject. Some of Mr. Kinsella's own theorizing—for instance, on referred pain, visceral neuroses, the "rule of superior location," and cutaneous hyperalgesia (the last partly based on an excursion into comparative anatomy)—seems to outrun our knowledge of the facts. But the rest of the book is of high value. The historical outline is illustrated by plates from the works of Vesalius, Eustachius, and Willis which put many of the figures in our modern books to shame.

The author emphasizes that the clinical study of pain is beset with difficulties and pitfalls. Pain is not just a simple sensation like muscle sense—it is accompanied by varying degrees of feeling-tone and drives. "Patients' fear and anxiety may cause the stimulation of pain or an exaggerated reaction to slight pain. The method of questioning, either the tone of the voice or the words used, may influence the patient both as to the presence and absence of pain, its degree, and its situation. A question may set the patient on edge and arouse his apprehension." A leading question may be indispensable to elicit information, but it may call forth a misleading reply. In surgical studies under local anaesthesia the patient's imagination is apt to conjure up fearsome pictures and to anticipate much suffering, and he may reply to questions in a manner calculated to safeguard himself from pain. A local anaesthetic may produce general effects: thus cocaine induces euphoria and damps down unpleasant reactions. The administration of morphine tends to suppress the slighter pains. Mr. Kinsella describes in detail his technique for operating and questioning under local anaesthesia. It may be added that once a pain is gone it is hard to recall accurately and fully; a pain "recollected in tranquillity" is merely an intellectual and emotionless simulacrum of the real experience.

The afferent innervation of the abdominal viscera is very sparse. Langley has calculated that all the afferent fibres from the viscera of the cat equal in number those in one posterior nerve root; it might be added that the fibres in all the posterior nerve roots equal in number those in the optic nerve. The visceral afferents are probably non-

medullated and finely medullated like those coming from the skin. Mr. Kinsella quotes John Hunter very aptly—"for distinct sensation, two things are necessary, namely, time and space." To arouse a sensation an adequate number of impulses must reach the brain in enough fibres over a given time to permit of "central spatial and temporal summation." In testing visceral sensibility one must therefore stimulate an adequate portion of a viscus sufficiently vigorously. There is also a great difference between the sensibility of a normal and an inflamed viscus.

These considerations may account for the discordant findings about visceral sensibility. Thus, squeezing with fingers or forceps, or stitching, cutting, or clamping the healthy appendix or caecum arouses no pain. When the appendix is inflamed squeezing it along a considerable part of its length produces pain. Wolf and Wolff similarly found that pinching the gastric mucosa or rubbing it with the blunt end of a glass rod is painless except when the stomach is inflamed and oedematous. Other observations by Kinsella on the large intestine and cervix uteri seem to prove that afferent impulses arising from certain viscera may give rise to pain—i.e., there is so-called true visceral pain. The pain fibres in the mesentery arise mainly in the gut wall itself; it is easier to produce pain by stimulating the mesentery than the gut, because in the former the fibres are concentrated in the vicinity of blood vessels while in the latter they are sparse and widely distributed. A localized stimulus applied to the gut will stimulate fewer fibres than one suitably applied to the mesentery, especially in the neighbourhood of its blood vessels. From what is known about the properties of pain fibres elsewhere it is likely that the visceral pain fibres will respond to a wide range of stimuli having in common the property of nociception. In states of inflammation the altered blood supply, oedema, and the presence of abnormal chemical products may facilitate the reaction of the pain fibres to appropriate stimuli.

Evidence is produced that the posterior pelvic peritoneum, especially over the right iliac fossa, is less sensitive than the anterior peritoneum to painful stimuli. This observation helps to explain why a retrocolic or retrocaecal inflamed appendix commonly gives rise to less pain than the normally placed organ. Mr. Kinsella discusses the mechanism of pain in peptic ulcer at some length, but no convincing conclusion emerges.

It would be well if clinicians bore in mind the limitation of physiological knowledge about pain mechanisms in general. Some account can be given of the properties of pain fibres and the course of the pain impulses from the periphery as far as the thalamus, but beyond that point our knowledge is meagre. We do not know what part of the brain is responsible for mediating either the sensation of pain or its emotional accompaniment. Stimulation of the postcentral cortex, or for that matter of any other part of the cortex, is painless. There is, however, some evidence from the results of prefrontal leucotomy that the prefrontal cortex or prefrontal-subcortical areas may be somehow concerned with the feeling-tone. Nothing is known with certainty about the way in which skin pain is normally localized with considerable accuracy. It is hardly surprising, then, that we should not know why pain of visceral origin is inaccurately localized, projected to somatic areas, or sometimes accompanied by cutaneous hyperalgesia. It is to be hoped that Mr. Kinsella and other surgeons with similar gifts and opportunities will continue to collect and record accurate studies of patients—perhaps leaving the grand generalizations to emerge gradually in their own good time in the future.

SAMSON WRIGHT.

THE FUNCTIONS OF PSYCHIATRY

Psychiatry. Its Evolution and Present Status. By William C. Menninger, M.D. (Pp. 138. 11s. 6d.) London: Geoffrey Cumberlege. 1948.

This volume of Messenger lectures founded to "share knowledge on the evolution of civilization" describes man's mental reactions and their influence on society. After early neglect psychiatry has now assumed a wide popular appeal in the U.S.A., largely because 2,000,000 young men were rejected from war service on account of personality disorders and 700,000 were discharged as unfit on this account.

The lectures begin with a brief historical survey of the rise of psychiatry and reflections on the imperfections in the teaching of this subject in relation to medicine at the present time. There are signs, however, that it is now beginning to be more effectively integrated with general medicine. The first lecture concludes with a discussion of the relationship of psychiatry with psychology, social science, anthropology, and religion.

The second lecture gives an account of psycho-analytic psychiatry under four headings—the psychosexual stages of development, the anatomy of personality in terms of the conscious and unconscious, personality physiology in terms of the id, ego, and superego (which are reasonably lucidly explained, though the concept still remains difficult to the non-technical reader), and some examples of the defence mechanisms used by the ego to maintain its equilibrium.

The third section is on psychiatry and the social order, and what can be done to improve human relationships in the post-war world. Often in mental stress a change in the environment is as important as a change in the personality, and psychiatry may show how the environment can be most wisely changed. Knowledge can only be gained by an intense study of the reaction of the individual to his environment. The importance of the family is stressed, and the increasing disturbance of family life is ominous. Disturbances in community life seem to be increasing, due to prejudices, hostilities, and such factors as housing shortages.

The prevention of mental illness is still in a backward state, though mental hygiene is making progress. The training of leaders and the instillation of the proper motivation and a spirit of service are essential to the welfare of the human race, and psychiatry can certainly contribute to these ends. These three lectures cover a vast field, but they are clear and sensible and well worthy of study by both medical and lay readers.

R. G. GORDON.

ENDOCRINOLOGY IN BRIEF

The Value of Hormones in General Practice. By W. N. Kemp, M.D. (Pp. 115. $3.) Minneapolis: Burgess. 1949.

This work describes itself as "prepared for the express purpose of assisting general practitioners in the fullest possible utilization of the many pharmaceutical hormonal preparations now available." It is not prepared in book form, but consists of cyclostyled typewritten sheets bound with wire rings. There are no illustrations (a disadvantage in a book on endocrinology), neither is there an index: there are numerous typing errors.

It is on matters of treatment that the book is least helpful. For example, Simmonds's disease (which responds well to testosterone and other hormones) has no treatment mentioned at all. Cushing's syndrome is also left devoid of therapy, and no mention is made of the adrenal, pituitary, basophil, ovarian, or thymus tumours that can cause it. The dose of thyroid for myxoedema is not specifically

mentioned except for the statement, "Forty-five grains (3 g.) of thyroid extract is the theoretical daily requirement of an adult with comp'ete athyrosis . . . smaller clinical doses are the rule," which might lead to overdosage. In connexion with pituitary dwarfism we are told, "Therapy is fairly satisfactory . . . a potent growth hormone should be administered daily . . . a growth rate considerable [*sic*] in advance of normal is desirable." Perhaps that will be true one day, but it is not true yet. The treatment of Addison's disease is quite well described, but the information that "all the thirty-nine vitamins should be present in the diet" might frighten readers that something awful would happen if they only managed to include thirty-eight. The poor balance of the book can be illustrated by there being only eight lines about the treatment of thyrotoxicosis, whereas there is more than twice that amount written about the prevention of neonatal death among sheep.

A heavy style makes the reading matter less digestible than it should be. A child, instead of being called "debilitated" or "poorly," is described as being "under a strain from concomitant biochemical or bacteriological influences"; and it would be easier to read, "Reduce the dose," instead of, "A downward revision of the dosage regimen is indicated." Though parts of the book are reasonably accurate and informative, as a whole it can hardly be recommended as a useful guide for students or practitioners of endocrinology.

RICHARD ASHER.

GUIDE TO CHEMOTHERAPY

The Sulphonamides in General Practice. By Edward D. Hoare, M.D. (Pp. 90. 5s.) London: Staples Press. 1949.

The preface to this book states that it is intended for the general practitioner, and that it attempts to indicate briefly the conditions under which sulphonamides will be valuable and the dangers which may attend their use. In addition, the relative merits of sulphonamides and penicillin are briefly discussed. The book is adequate for this purpose, and it sets out in brief, simple language most of the information which the general practitioner requires. The main principles of sulphonamide therapy are now so well established that it is not possible to be original on the subject without becoming unsound; and, if some of the statements made seem platitudinous, this is because they repeat many of the recommendations given in various previous books on this subject (although no acknowledgment is made to these sources). The book is briefer than the M.R.C. Memorandum on the sulphonamides and it contains up-to-date minor details. The arrangement of the specific infections according to whether they are more, equally, or less susceptible to sulphonamides than to penicillin is somewhat confusing. There are a few minor misprints which are disfiguring rather than important. The book can be recommended as a concise elementary guide.

F. HAWKING.

Modern Discoveries in Medical Psychology, by Dr. Clifford Allen (pp. 236; 12s. 6d.; London: Macmillan, 1949), is the second edition of a book published twelve years ago with the object of explaining in simple language the theories and practice of medical psychology to general practitioners and students. It says much for the generation of psychiatrists, as they would now be called, of which the author is a distinguished member that such a book is much less necessary now than when the lectures on which it was founded were first delivered. Nevertheless, it is still interesting and affords us a good review of the development of the treatment of mental illness, especially psychoneurosis, which has taken place in the last half-century. Some remarks which were no doubt apposite when first written now seem out of place and might well have been omitted—for example, few contemporary neurologists seek to find a cerebral localization for hysteria.

BOOKS RECEIVED

THE USES OF STREPTOMYCIN

Streptomycin is now freely obtainable in this country, and the profession as a whole is consequently in a position to make valuable use of it. At the same time there are possibilities that this expensive and by no means harmless drug may be either wasted or used in such a way as to do positive harm, and therefore its properties and indications should be kept under careful review. Streptomycin, like penicillin, is usually administered by intramuscular injection, and for most purposes, owing to its slower rate of excretion, two daily doses suffice. There is no streptomycin equivalent to procaine penicillin, with a therapeutic effect lasting 24 hours or more, though a single daily dose has sometimes been used. Unlike penicillin, its dosage has to be kept within strict limits if serious toxic effects are to be avoided: the most notable of these is on the eighth nerve, causing vertigo and disturbance of position sense and even deafness, either of which may be permanent. It is in fact a much more harmful and also a less potent chemotherapeutic agent than penicillin, and would find no place in therapeutics but for the fact that it acts on many bacteria against which penicillin is powerless.

Foremost among these is the tubercle bacillus. Much could be written about the indications for using streptomycin in tuberculosis, but they depend on two principles which can be expressed shortly. One is that the more acute the disease the greater is likely to be the effect. This probably has much to do with the fact that in the early stages of any rapid extension of the disease the bacilli are more accessible to a drug reaching the affected area through the blood: large areas of tissue have not undergone caseation and so formed a mass remote from any blood supply and therefore partially or wholly impenetrable by the drug. The strongest indications for streptomycin therapy, both on this ground and of course because they are otherwise fatal, are the miliary form of the disease and tuberculous meningitis. Rapidly extending pulmonary infiltration and ulcerative tracheo-bronchitis also call for streptomycin treatment. But when it is contemplated in a more chronic case, whether of phthisis or of the disease elsewhere, the object should be clearly defined and streptomycin administration specifically related in time and intention to other treatment, particularly surgical. Thus in advanced phthisis with extensive cavitation streptomycin may sufficiently improve the condition to make possible a thoracoplasty which could not have been undertaken before, but it should not be used until plans for this have been completed. It may be very difficult to resist the demands of patients and relatives for the new "wonder drug," but if these demands are infrequently resisted and treatment of tuberculosis with streptomycin becomes at all indiscriminate the ultimate effects will be disastrous. A warning to this effect was given in the letter of Dr. B. Couts published in a recent issue (October 22, p. 933). The fact to be borne constantly in mind is that only one chance is usually given of killing any particular tubercle bacillus with this weapon. In the majority of patients bacilli surviving at the end of a course of treatment are found to be resistant to the drug, and remain so indefinitely. This change precludes the further treatment with streptomycin both of that patient and of anyone else whom he may infect. Several instances of infection with streptomycin-resistant bacilli in contacts of treated cases have already been observed in the United States. It is unfair to the whole community to use streptomycin in patients with open tuberculosis unless for good and well-defined reasons. The decision to use it is emphatically one for the expert only.

The other uses for streptomycin are almost all included in a category which can be defined only in bacteriological terms—infections due to Gram-negative bacilli, the majority of which are little affected by penicillin. These are numerous, but some of them are either unknown in this country or uncommon. It is in tularaemia that streptomycin has had perhaps an unqualified success, but in this country we cannot exploit its usefulness either in this disease or in plague. Its disappointing effect on enteric fever is difficult to explain, but fortunately another antibiotic, chloramphenicol, has a remarkable action in typhoid.[1] Given with sulphadiazine, streptomycin will cure brucellosis, but the same effect can be achieved more simply and safely with "aureomycin." Among uncommon conditions in which streptomycin is indicated are *H. influenzae* meningitis, pneumonia due to Friedländer's bacillus, and either septicaemia or meningitis caused by such organisms as *Proteus* or *Ps. pyocyanea.*

What are the commoner conditions, other than tuberculosis, in which streptomycin may be called for? They fall into three categories—certain intestinal infections, infections of the urinary tract, and some conditions due to penicillin-resistant cocci. When streptomycin is swallowed it is neither absorbed nor destroyed, but acts as a remarkably efficient intestinal antiseptic. It undoubtedly has a beneficial effect in

[1] *British Medical Journal*, 1949, 2, 918.

bacillary dysentery, and possibly in *Salmonella* infections other than enteric fever. Its action in infantile gastro-enteritis is a subject of controversy, possibly because there is more than one cause. It may be said that this type of use is justified only in severe cases which have been investigated as fully as possible. Most bacillary dysentery seen in this country is too mild and self-limited to deserve so costly a treatment. In ulcerative colitis streptomycin is useless. Urinary-tract infections are a different matter: owing to their frequent intractability the controlled use of streptomycin is fully justified. Whether such control is practicable outside a hospital is exceedingly doubtful. Urological investigation is first necessary to identify any underlying cause: no drug can be expected to eliminate infection in the presence of obstruction or a calculus. Examination of the urine should include determination of the sensitivity of the organisms to streptomycin and possibly to other drugs which merit trial first. It is then necessary by medication to render the urine consistently alkaline, since streptomycin is relatively inactive in an acid medium. Finally, the drug has to be given intramuscularly, and preferably—though there is singularly little information on this important point—three times a day at least. Even when such care is taken treatment with streptomycin sometimes fails, usually because some underlying cause has not been eliminated. How often, then, is success to be expected from a few intramuscular injections given optimistically to an ambulant and incompletely investigated patient? Laboratory and often other hospital facilities are also required for the investigation and treatment of the third group of infections which may be benefited by streptomycin: coccal infections normally responsive to penicillin but sometimes resistant to it. The majority are staphylococcal, though streptomycin may have a use in certain streptococcal infections. It has even been used in the treatment of penicillin-resistant bacterial endocarditis.

There are thus comparatively few conditions in which streptomycin can justifiably be used for a patient outside a hospital. Within hospital, though indications may be more numerous, the grounds for administration should be well ascertained and weighed. This warning is called for not merely because the production of streptomycin even in England means dollar expenditure, and waste is therefore the worst form of extravagance, or even only because the drug is potentially dangerous: the strongest objection to indiscriminate use is that already mentioned in connexion with tuberculosis—that unsuccessful treatment renders the organism completely resistant. The tubercle bacillus rarely acquires this property in less than about six weeks. Other bacteria, multiplying at a far greater rate, can acquire it within a few days or even overnight. The trial of streptomycin for a urinary tract infection, for instance, without proper safeguards can do a patient irreparable harm by placing him out of reach of even properly controlled treatment later. In time, no doubt, resistant bacteria of other species than the tubercle bacillus will be transmitted from person to person, and infections in untreated patients will be found totally resistant at the outset. It is even possible that the use of the drug will have to be altogether abandoned on this account in the not far distant future. Fortunately there is no other antibiotic or drug of any kind to which such high resistance can be acquired so rapidly, just as there is no other which can become an essential nutrient for an organism on which its previous action was destructive. This almost ludicrous transformation is now fully substantiated and known to occur in many species, including the tubercle bacillus. Nothing illustrates more clearly than this how fragile a weapon streptomycin is and how ill-defined is the boundary separating good from harm in its effects. Doctors possess in streptomycin something quite peculiar and not to be regarded in the same light as any other drug. It should be reserved for use only on the clearest indications and under the closest observation. Every patient treated unsuccessfully brings nearer the day when no patient will be able to be treated with streptomycin at all.

RECRUITMENT OF MEDICAL OFFICERS

The recommendations of the Spens Committees are exerting their influence far beyond the terms of reference that the committees considered. Organizations outside the Health Service competing to employ medical men—such as the universities, the armed Forces, and industrial firms—are finding that they must offer terms at least as attractive as those offered within the Health Service. Though it is doubtful whether remuneration in the Health Service fulfils the Spens recommendations in terms of the present value of money, a number of universities have found it necessary to increase the salaries paid to medical men, and the British Medical Association has made out a strong case that the armed Forces should do likewise.

Recruitment of regular medical officers to the Army, which is at an exceedingly low ebb, suggests that the financial terms offered must be improved if the Army is to be able to attract sufficient doctors, and there is reason to believe that that view is held in the War Office. The decline in recruitment can be accounted for in part as an inevitable post-war phenomenon. Research at the War Office has shown that recruitment has always fallen off after great wars, including the Crimean War, the Boer War, and the two world

wars. Though the total number of medical officers in the Army is at present sufficient for the establishment of 1.5–1.75 per thousand population at risk (which does not comprise only British troops), the number of regular medical officers is slightly below strength, and that of short-service officers is just over 60% below. The total numbers are likely to fall to about 10% below establishment by next January. The deficiency of regular officers is at present made up from National Service officers, whose work is highly praised at the War Office; they constitute about 50% of the total. This flow cannot continue in sufficient volume, for the shortage of vacancies in medical schools induces a considerable number of students to do their National Service before starting a medical course, so that they are not available to be conscripted as medical officers when they have completed it.

Specialists are particularly scarce, and the Army has recently advertised for civilian specialists at salaries that are distinctly attractive compared with those paid to medical officers, as correspondents to this *Journal* have pointed out. It is of interest to record that no specialist was appointed as a result of that advertisement, but so great is the need for them that the Army will probably continue the policy, as a temporary measure, of offering appointments to civilians. The Armed Forces Committee of the Association has considered whether it should recommend refusal of this kind of advertisement, but decided not to do so—at least for the present—in view of the Army's urgent need. It may take a different view if the Government fails to solve the Army's problem. Meanwhile many opportunities are given the regular officer to gain special experience and higher qualifications. They include study leave and work at suitable training centres, and the short-service officer is also encouraged to specialize. In all, about one-third of the regular and short-service officers are trained in this way.

The Ministry of Defence is now considering the B.M.A.'s proposals[1] for new scales of pay in the three Services. The increases proposed as a minimum range from 3s. a day in the lowest ranks to 27s. in the ranks of surgeon-captain, brigadier, and air commodore, with smaller increases in the ranks higher than those. The Government's reply is expected shortly, but the Ministry has already notified[2] the B.M.A. that remuneration of personnel in the armed Forces is decided by the Government, and that negotiations with bodies representing any section of the Forces have never been undertaken, since they would be incompatible with Service discipline. This attitude seems more calculated to frighten than to inform, for the Ministry can hardly be expecting the Association to incite its members in the Forces to sedition. No objection can be taken to the analysis of evidence and the preparation on it of a carefully reasoned case, particularly when the adoption of the Association's proposals is likely to encourage recruitment and thereby benefit the medical arms of the Services.

Though the country is in difficult circumstances economically there is no evidence that the Government intends to allow the Forces to fall below the strength vitally necessary for defence, nor would the nation allow it to do so. Further economy in medical man-power would seem to be impossible. Overlap between the three Services has already been largely eliminated; in small stations one of the Services is normally responsible for the medical care of personnel from all three, and at home the Forces co-operate with National Health Service hospitals and practitioners. The Government must therefore offer attractive terms if it is to fulfil its duty of providing adequate medical care of the armed Forces.

ANAESTHETIC EXPLOSIONS

The risk of anaesthetic explosions should by now be well known in view of the attention it has received in recent years. In his review of the literature some four years ago Cole[1] was able to list 70 papers on this subject. They ranged from brief accounts of simple accidents in which only the doctor was damaged[2] to Greene's analysis of 230 anaesthetic fires and explosions.[3] Yet every year there are a number of anaesthetic explosions, many of which must needs be reported to the coroner. Every junior anaesthetist and probably most medical students know that the common inhalation anaesthetics used in this country—ether, cyclopropane, and ethyl chloride—are inflammable, and when mixed with oxygen explosive. Everybody knows that heat, or a spark, or a naked flame is needed to touch off an explosive mixture. It might thus appear that explosions would never occur in operating theatres, for who but the completely uninitiated would bring an explosive vapour and a source of ignition together? Yet this is what happens only too often. Two anaesthetic explosions have been reported this year[4]; many explosions in which there is no loss of life go unrecorded, though doctors, nurses, and onlookers may

receive injuries varying from singed hair to the loss of an eye from flying glass. The patient may be spared or may suffer fatal blast injuries of the respiratory tract.

The dangers of static electricity, which was responsible for one of these two explosions,[5] are not yet generally appreciated. These electrical charges accumulate quickly and easily on insulated objects in an operating theatre. Complacency about static electricity was produced by a once common teaching that this phenomenon occurred only in countries with a very dry climate. We know better now, and even on the dullest, dampest day a little effort in an operating theatre in smartly pulling a blanket across the top of a theatre trolley will produce a spark when a finger is held about one-sixteenth of an inch away from the metal top of the trolley. The same effect may be obtained when an anaesthetized patient wrapped in one or more blankets is lifted from a trolley to the operating table. For this reason Waugh and Bond[6] recommend that woollen blankets should never be used in the operating theatre. These static charges may be dispersed or prevented from accumulating if certain simple precautions are adopted, one of which is the fitting of earthing chains dangling on the floor to every insulated movable object in the operating theatre. Surgeons and anaesthetists become insulated movable objects when they wear rubber-soled boots and shoes; all such footwear should have soles of conducting rubber, and boots of this sort are now obtainable. When the humidity of the theatre is kept as high as is compatible with working comfort the accumulation of static electricity is again less likely to occur.

Obvious sources of ignition abound in operating theatres. There are such old offenders as the sparking diathermy needle, and even the apparatus itself may be a danger, particularly when spark gaps are visible through a perforated metal case. These things must obviously be avoided in the presence of explosive vapours. Less well known is the risk associated with endoscope bulbs, which are so often overloaded because the surgeon wants more light. Ether vapour can be ignited by a temperature as low as 172° C., and these little bulbs may become very hot. Such a bulb may also break, with the momentary exposure of a white-hot filament. A simple device fitted to the voltage reduction apparatus will prevent their being damaged by overloading. Endoscopic instruments should also be inspected regularly to ensure that the lamp and the lamp-holder fit perfectly; a defective contact at this point may be responsible for touching off an explosive anaesthetic mixture.[7]

Less obvious sources of ignition are numerous and cannot all be tabulated here. Surgeons often use appliances like electrical saws, drills, cauteries, and lights without considering whether these instruments are safe or otherwise from the point of view of setting off an explosion. No such device should be introduced into the theatre until it has been approved by a trained physicist or an engineer who could say whether or not there is danger of an explosion when the instrument is in use. In the same way an expert electrician should inspect regularly the switches and plugs in operating theatres. Loose connexions and deficient earth connexions can then be made good. It is perhaps hardly necessary to state here that open-flame sterilizers should never be used in theatres and anaesthetic rooms. Much has been written about all these and other precautions. Were they all adopted explosions would be very rare. But lack of awareness on the part of surgeons, anaesthetists, hospital administrators, and theatre sisters still continues. The surgeon who enters the anaesthetic room with a cigarette at his lips would not be welcomed in any factory where there was the same risk of explosion, and there are certainly some anaesthetists who would regard such conduct as "entirely inexcusable."[3] When an obvious source of ignition must be present expert anaesthetists can usually administer satisfactorily a non-inflammable anaesthetic. Thus in one explosion the diathermy needle was applied near the pleura in a patient who had recently had a pneumonectomy. The possibility of a bronchial fistula being present in such a case is well known, and the use of an explosive mixture like cyclopropane and oxygen in these circumstances is surprising. Chloroform, thiopentone, nitrous oxide, and curare, all non-inflammable, are commonly employed in thoracic centres all over the world, and it seems that in this instance the use of one of these might have prevented the explosion. In cases of this kind the diathermy point and the explosive vapour may be separated only by thin pleura and the surgeon's steady hand. It is by no means certain that the risk attached to non-explosive anaesthetics in such cases is greater than the risk of explosion.

Anaesthetic explosions continue to occur despite all the publicity that has been given to the subject in the medical literature and in the newspapers. It should perhaps be considered whether the precautions now generally accepted should not be made a legal responsibility of hospital authorities and of those working in operating theatres. Thus, deaths resulting from their non-observance might at least raise the possibility of salutary penalties. Interest in the prevention of explosions would then be given new impetus. When the Ministry of Health issued a memorandum[9] on this subject before the war it had to be addressed to medical officers of health and local authorities. The Ministry is now more intimately concerned than ever before with hospital activities, and might perhaps be stimulated to consider again the problem of anaesthetic explosions and the avoidable deaths which are caused thereby.

MALIGNANT HYPERTENSION

There is a growing conviction that malignant hypertension is a form of primary hypertension not preceded by structural renal damage but causing it. This is a result of careful clinical and histological studies of early cases, and recently Byrom and Dodson[1] have put forward experimental evidence which gives further support to the theory. In malignant hypertension acute focal necrotic lesions occur in the terminal arteries and arterioles of many organs, especially in the kidney, where the glomerular vessels are affected and tubular changes develop. Byrom and Dodson studied the onset of this acute necrotizing arteritis in the hypertensive animal and demonstrated the aetiological importance of increased intravascular tension: neither uraemia nor "toxic" absorption from damaged renal tissue was a necessary or constant precursor. Other writers consider that the characteristic arterial necrosis will not occur unless renal abnormalities are present—despite the finding of such necrosis in the early stages of the natural disease in patients with otherwise clinically and histologically healthy kidneys. Some even believe that the renal factors alone are concerned and that increased intravascular tension is not.

In their first series of experiments Byrom and Dodson used the Goldblatt technique to produce hypertension in eight young rats. The left kidney was rendered ischaemic by constriction of the left renal artery with a cotton thread ligature; the right kidney was undisturbed. The animals were killed after periods of 3, 7, 10, 14, and 17 weeks, during which time the systolic blood pressures were recorded. In every animal some atrophy of the ischaemic kidney was found, but no arterial lesion. There were necrotizing arterial lesions in the intact (right) kidney of six rats and in the heart, mesentery, brain, and spleen in a similar number. The finding by Schroeder and Neumann[2] and Patton and his colleagues[3] of necrotizing lesions in both kidneys can be explained as the result of variation in the ligation of the left renal artery. As Byrom and Dodson have shown, effective ligation acts as a barrier and protects the left kidney against the increased arterial tension. In an endeavour to find out how hypertension causes the arterial necrosis, they tested the hypothesis that a consequence of sudden overstretching of the vessel wall, as may occur when the intravascular tension is increased, is necrosis of the overstretched muscle and lysis; blood and plasma then seep into the affected zone and are transformed into a fibrinoid plug by the action of thromboplastin from the damaged muscle. Two millilitres of warm Ringer's solution was injected through a short bent needle (0.6 mm. bore) ten to fifteen times into the exposed left common carotid artery of 23 young adult rats; the injections were made towards the heart—the upper end of the artery being ligated. In 10 of the animals a loop of thread round the left renal artery was pulled taut during the injections, thus protecting the left kidney against the sudden increased tension. The transient rise in pressure which resulted probably amounted to between 80 and 90 mm. Hg. During the injections, which were made as forcibly as possible, the cortex of the kidney was seen to blanch momentarily and equally briskly to regain normal colour. After repeated injections, however, small irregular areas of residual pallor were noticed which returned to normal more slowly owing to transient spasm of the intralobular arteries. The animals recovered quickly and appeared well when killed three days later. Typical acute focal fibrinoid necrosis of the arteries of the cortex, including the afferent glomerular arterioles, was found, except in the kidneys protected by occlusion of the renal artery. A clear demonstration of the sequence of events leading to the appearance of the lesion was obtained—necrosis of a segment of muscle cells with autolysis, and with fibrinoid exudation into the adventitia and subintima with or without round cell and fibroblast infiltrations. Occasionally simple coagulative necrosis occurred. No hypertensive glomerular lesions were seen: the parenchymatous damage was limited to slight tubular degeneration—a clear indication of the brief duration of arterial contraction. This is a most important observation, since there is clinical belief that the acute symptoms in malignant hypertension, especially those associated with encephalopathy, may be caused by transient vasospasm.

Other experiments of Byrom and Dodson confirmed the findings of Leiter and Eichelberger[4] that bilateral renal-artery ligation causes earlier death (48 hours) than bilateral nephrectomy (76 hours), and that necrotizing arteritis (of pancreas and other viscera) may occur after ligation of both renal arteries or both ureters. This shows that the arterial and arteriolar lesion can arise in the absence of gross hypertension as a result of total renal insufficiency and total necrosis of the kidney. But this combination is never present in either experimental or human hypertension. Braun-Menéndez and his colleagues[5] suggest in an ingenious hypothesis that arterial necrosis may develop from a combination of two of the three factors—hypertension, uraemia, and the toxic absorption of dead renal tissue. But this does not explain the appearance of the arterial lesion in experiments where hypertension alone is present. While admitting that both uraemia and renal necrosis may play a secondary part in the "malignant" termination of chronic renal hypertension and may accelerate the late stages of true malignant hypertension, Byrom and Dodson interpret the results of their experiments as good evidence for the simple mechanical explanation of acute hypertensive vascular lesions. Their work supports the modern clinical concept of malignant hypertension and the assumption that the difference between benign and malignant hypertension is simply one of degree.

ACUTE MASTOIDITIS IN CHILDREN

The sulphonamides and penicillin have changed beyond recognition the prognosis and treatment of acute infections of the middle ear cleft. Nevertheless each new chemotherapeutic substance has its drawbacks as well as its advantages. The drawbacks are not always apparent at first, as witness the masking of symptoms in acute mastoiditis and the increased risk of deafness from otitis media before this was recognized as a possible danger. It is now accepted

that these complications may largely be avoided by adequate early dosage and prompt drainage of pus. The latter may be unnecessary if chemotherapy is instituted early enough, but all authorities reiterate the need for drainage of pus. Elsewhere in this issue Mr. A. J. Moffett and Dr. G. A. Dalton report the results of treating acute mastoiditis in children with penicillin and sulphadiazine. They included in their series every case of undoubted acute mastoiditis seen in hospital over a period of three months. In addition to systemic disturbances, tenderness, swelling, oedema, and, in some cases, a fluctuating abscess over the mastoid process were present: the typical downward and forward displacement of the pinna was seen, to a greater or lesser extent, in all the cases. The children were treated in hospital with full doses of sulphonamides and penicillin in addition to local cleansing and penicillin aural drops thrice daily. Myringotomy was performed when necessary. Out of 17 children, whose ages ranged from 18 months to 12 years, treated in this way all except one were cured without surgical drainage of the mastoid. The otorrhoea ceased in an average of 5.6 days (limits, 3 to 11 days), the periostitis in an average of 8 days (limits, 5 to 11 days), and the drum recovered its normal appearance in 13 of the cases in an average of 10.7 days (limits, 8 to 19 days) from the beginning of treatment. In all cases the parents were written to several months after discharge of the child from hospital in order to find out if there had been any lighting-up of the infection, but none had occurred. The saving of suffering to these children and the reduction in time spent in hospital are obvious advantages, but the risks of treatment should be borne in mind. As the authors point out, a careful watch must be kept throughout for signs of intracranial suppuration, and before this method can be generally applied further trial should be made of it in hospital. There will always be need to take special care that the often ill-defined signs of continued suppuration or its intracranial spread do not go unnoticed. The possibility of using this method of treatment in adults may be considered, but it should be remembered that because of the greater vascularity of the temporal bone in a growing child the reaction to infection caused by organisms sensitive to chemotherapeutic substances will probably be more favourable in children than in adults.

AUREOMYCIN AND SYPHILIS

Supplies of aureomycin have until recently been scarce in this country, and little has therefore been published here on its use in the treatment of various diseases. The report by Dr. R. R. Willcox which appears on another page is probably the first to be published in England about the treatment of early syphilis with this drug. Willcox treated nine Bantu negroes suffering from primary or secondary syphilis with doses of aureomycin ranging from 0.75 to 1.5 g. over periods of 24 to 48 hours and noted that lesions, especially secondary ones, healed rapidly and that spirochaetes disappeared from surface lesions in 48 hours. Unfortunately follow-up examination was impossible, so that the effect on serum reactions could not be observed. One patient with secondary syphilis relapsed after 12 days. In the U.S.A. O'Leary and his colleagues[1] reported two cases of syphilis treated with aureomycin. The first, a case of secondary syphilis, was given 44.2 g. of the drug in 16 days: a mild Herxheimer reaction occurred after 24 hours. Spirochaetes disappeared in 60 hours, and a scrotal lesion healed in 26 days; but serum reactions, though weakening, were still positive after 41 days. Side-effects included nausea and anorexia. The second case treated by these authors was one of primary syphilis. This patient received 67.5 g. of aureomycin in 15 days; spirochaetes disappeared after 16 hours, and the primary sore healed in 15 days. Reactions were similar to those in the first case. In experiments on rabbits infected with *T. pallidum* 10 to 14 days previously Wiggall and his colleagues[2] found that intramuscular injections of aureomycin (50 mg. per kg. of body weight) caused lesions to heal and spirochaetes to disappear, though rather slowly. They also treated 15 patients suffering from primary or secondary syphilis with doses varying from 18 to 36 g. for two to six days. Again spirochaetes disappeared rather slowly, in some cases persisting for nearly 72 hours, but most lesions healed in six days. Side-effects were mild in men, but the drug was toxic for rabbits, possibly because it was given parenterally.

Aureomycin is best given orally in the form of 250-mg. capsules, and toxic effects in human beings appear to be slight, consisting only of nausea or vomiting, anorexia, and diarrhoea. The drug undoubtedly has an effect on syphilis, but its relatively slow action in killing spirochaetes suggests that it is not nearly so active a remedy as penicillin or arsenic. Its influence on serum reactions and its action in late, neuro-, and cardiovascular syphilis will not be known for some time. Meanwhile its use in the treatment of human syphilis must still be experimental, and no attempt to give it as a routine can be justified until more is known about dosage, period of administration, and possible toxic effects. In this connexion it is of interest to note that aureomycin is effective in all five venereal diseases—syphilis, gonorrhoea, chancroid, lymphogranuloma venereum, and granuloma inguinale.

Sir Herbert Lightfoot Eason, President of the General Medical Council, died on November 2. An obituary notice is published in this issue of the *Journal* at p. 1117. The next meeting of the Council over which Sir Herbert should have presided will open on Tuesday, November 22, at 2 p.m.

Dr. Donald Hunter will deliver the Ernestine Henry Lecture before the Royal College of Physicians of London (Pall Mall East, London, S.W.) on Tuesday, November 15, at 5 p.m. His subject is "Devices for the Protection of the Worker against Injury and Disease."

Dr. Norman B. Capon will deliver the Charles West Lecture before the Royal College of Physicians of London (Pall Mall East, London, S.W.) on Tuesday, November 22, at 5 p.m. His subject is "Development and Behaviour in Childhood."

REFRESHER COURSE FOR GENERAL PRACTITIONERS

MANAGEMENT OF THE PREMATURE BABY

BY

ALAN MONCRIEFF, M.D., F.R.C.P.

Nuffield Professor of Child Health, University of London

According to official figures twice as many premature infants die each year in Great Britain as the total number of all persons killed on the roads. This indicates the seriousness of the problem. Half of these deaths occur in the first 24 hours of life and present a challenge to the obstetrician to prevent premature labour, but better management of the survivors would go far to reduce the loss of life. Although figures in connexion with prognosis are somewhat contradictory, the position can be summed up by saying that except for a slightly increased risk of cerebral trauma at birth the prematurely born infant has as good a chance as any other baby of growing into a normal and useful citizen.

Details of management to be discussed here are deliberately planned for what may have to be carried out in the patient's home. Some think this is a better place for premature babies than a hospital; others believe that the hospital can offer facilities and apparatus far superior to those available in a house. This should have been remedied to some extent since 1944,[1] when local health authorities were advised to keep certain appliances on hand for use in the home. A general practitioner called upon to look after a premature baby should certainly contact the medical officer of health for the district and see what apparatus he can get, and the services of a paediatrician should be available to lend expert help if required. More important than any apparatus and the aid of the expert, however, is good nursing. Some midwives are more skilled with small babies than others, and it may be possible to secure the services of one who has had special experience with premature babies—for example, at a maternity hospital with a special unit for their care.

General Management

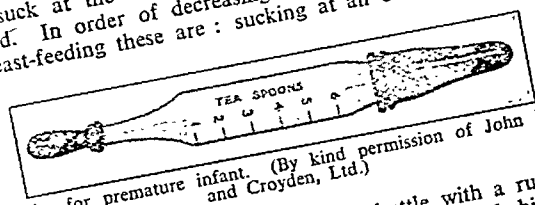
If premature labour has set in and a small baby is expected certain preliminary steps can be taken. It is wise to give the mother a dose of vitamin K. A cot or basket should be prepared with lined sides to prevent draughts. If time permits an oxygen cylinder should be obtained, with a close-fitting rubber mask or a nasal catheter for administration.

After the baby is born it should be wrapped in a warm towel and placed head downwards in the cot or basket, which should be suitably tilted. Gentle wiping out of the mouth and gentle aspiration with a rubber catheter will make sure that the air passages are clear. If available, oxygen may be administered for a short period to produce a good saturation of the arterial blood. If respiration is feeble carbon dioxide from a "sparklet" apparatus may be used, or some device improvised to secure a degree of rebreathing.

It must be remembered from the start that the greatest enemy is infection, and in the early days the nurse and doctor should wear an efficient mask and conduct all manipulations with an aseptic or antiseptic technique.

[1] Ministry of Health circular 20/44.

The room in which the baby is to be nursed must be kept warm—70 to 75° F. (21–24° C.) is ideal—in addition to the careful use of hot-water bottles in the cot or the employment of an electric blanket pad (which can be hired in some areas). The aim is to keep the baby's rectal temperature not below about 98° F. (36.7° C.), but this is sometimes not achieved for a few days. The temperature should certainly be taken and recorded four-hourly. The atmosphere must also be kept moist enough to minimize "evaporation" from the baby's skin and lungs. A wet towel hung over the back of the chair, with its end in a bowl of water and placed near a source of heat, will provide a reasonable degree of humidity. A bathroom, if available and able to be temporarily set apart for the baby, is often ideal because of its humidity.



When the baby has recovered from the initial shock and is breathing well and a good colour the nurse may give it a gentle cleansing. This is most efficiently accomplished as a modified blanket bath with soap and water and a soft flannel, exposing only a small portion of the skin at a time. Drying should be carried out by gentle dabbing with a warm, soft towel, followed by a suitable baby powder (olive oil is messy, an inefficient cleaning agent, and not always sterile). The normal procedures for care of the eyes and cord should be carried out. Napkins can be applied, and the baby dressed in a gamgee jacket, bootees, gloves, and a bonnet, leaving only the face exposed. The bedclothes must not be too heavy. Before this dressing-up, however, the weight should be obtained if the baby's condition permits, for it is a most valuable base-line from which to judge subsequent progress. The infant should now be left in its cot and disturbed as little as possible, except to be moved from one side to the other from time to time to promote full expansion of the lungs. Oxygen may still be required at intervals if the colour does not remain good.

All these measures are necessary at first, but from the start the programme of management must be designed to speed up the process of maturation. That is to say, the baby must be brought daily nearer to the normal standards of care of the full-time infant. The external temperature of the room can be gradually lowered, some of the gamgee clothing cut away, and hot-water bottles or blanket pad left out of the cot for brief but increasing periods. It is difficult to lay down precise details to cover premature babies of all weights. Careful judgment is required, and the experience of the nurse is invaluable. I must stress the necessity for making progress and not keeping the baby too long before his own heat-regulating mechanism is called upon to take action.

Feeding

The same difficulty over precise details arises in connexion with feeding. Certain general principles will be discussed and, as far as possible, their application to a group of infants whose weights range from 2 lb. (1 kg.) or less up to the official standard of 5½ lb. (2.5 kg.).

Methods.—Most premature infants are too weak at first to suck at the breast, so that easier methods must be tried. In order of decreasing strain on the baby, after breast-feeding these are: sucking at an ordinary bottle;

Feeder for premature infant. (By kind permission of John Bell and Croyden, Ltd.)

the use of a Breck feeder (a small bottle with a rubber nozzle at the end opposite the teat, like the old-fashioned fountain-pen filler, by which positive pressure can be exerted); a spoon or pipette to drop the feed into the mouth; or tube-feeding by a catheter passed down the oesophagus through either the nose or mouth.

The first thing to establish after the baby is born is whether or not he can swallow. A little sterile water from a spoon can be tried. If there is no swallowing reflex, tube-feeding will clearly be necessary. If the baby can swallow, the next thing to ascertain is whether or not sucking can be carried out. If sucking proves possible a Breck feeder is the simplest apparatus: if not, a spoon or tube should be used according to the ability to swallow. The experienced nurse can soon determine a way of mixing the methods of feeding—one or two tube feeds and the rest by spoon, or starting the feed with a bottle and finishing with a spoon when the baby gets tired of sucking. Here, too, progress must be made and each day should see an attempt to take the baby a stage up the scale—tube, spoon, bottle—with the object of getting him to the breast.

Feeds.—Breast milk is the safest and most easily digested food. All premature babies should receive it at first even if it cannot always be continued. For the first 24 hours sterile water in small sips should be used, and during this period efforts to secure a supply of breast milk can be made. Only a few ounces a day will be required at first and should be obtainable without much difficulty from any nursing mother or from a maternity unit. It should be boiled and diluted to one-fourth strength for the very small babies and to one-half strength for the medium and larger-sized infants. Meanwhile the baby's own mother's supply of colostrum and milk should be obtained by manual expression.

By the end of a week or 10 days the breast milk can be given undiluted. If a supply proves impossible to obtain and no more can be got from the baby's own mother an alternative has reluctantly to be used. To avoid subsequent changes a choice should be made of a dried milk, either one of the so-called humanized varieties or a half-cream brand. These dried milks have the additional advantage of being obtainable at the local welfare centre. Either of these milks can be given from the second or third day of life and in a dilution which may vary from an eighth or quarter-strength, according to the baby's size, up to half-strength. One measure of milk powder to an ounce (30 ml.) of water may be assumed to be full strength. An attempt should be made to increase the strength daily, aiming eventually—in the second or third week—at full strength for the humanized brand and three measures to 4 oz. for the half-cream variety.

For simplicity, the addition of substances to the milk is not recommended. Some authorities prescribe additions of soluble caszin and others prefer to use evaporated milk, sweetened or unsweetened, but the programme outlined above works well and, as has been said, minimizes changes when the infant is older.

Times of Feeding.—Quantities and intervals of feeding are related. It must be remembered that small babies require relatively more food than full-term infants. If the basis for a 7-lb. (3 kg.) baby is 2½ oz. of breast milk per pound (150 ml. per kg.) body weight per day, then the smaller infant may require as much as 3, 3½, or even 4 oz per pound before a steady weight gain is achieved. But, as with normal babies, such a full feed programme should not be attained too quickly. If the largest feed, in volume, is achieved by the seventh to tenth day, this is usually safe If dried cow's milk is being used progress should be slower and for the smallest babies the full size (and strength) not reached until a little later. Provided that no oedema develops the weight curve is a most valuable guide and the experienced nurse can increase the strength and size of the feeds to keep pace with the strength and requirements of the infant. With the smallest infants this will usually mean beginning with feeds of 30 to 60 minims (1.8–3.5 ml.) every hour by day and two-hourly by night. Gradually this is increased to ½ oz. two-hourly by day and three-hourly by night, until 1 oz. is taken every three hours round the clock If the mother's milk supply has been established the infant may be tried at the breast at least once a day if over 4 lb (2 kg.) in weight at birth, or when this weight is achieved Even smaller babies, especially if twins (and therefore relatively more mature than the weight indicates), can suck quite strongly under this weight.

Whatever the feed a start should be made with vitamin supplements when the infant is a month old. Vitamin C as ascorbic acid in 25-mg. daily dosage can safely be given even before this. Vitamins A and D are best given as a vitamin concentrate to allow 1,000 to 2,000 units of vitamin D daily, and such dosage—twice the requirements for a full-term baby—should be continued throughout the first year. Iron is also best administered early, say at two to three months, and given in Mackay's mixture in a dosage of 1 gr. (65 mg.) three times a day.

Two other medicaments are also worthy of mention Some paediatricians give all babies vitamin K after birth to prevent hypoprothrombinaemia, and, as already suggested above, if premature labour is anticipated this vitamin can be given to the mother also. Thyroid extract has a useful part to play. If the baby is particularly sluggish and difficult to rouse and has a subnormal temperature, the metabolism can certainly be stimulated by giving the equivalent of 1/10 gr. of thyroid extract per pound (14.4 mg per kg.) body weight daily. This should generally be administered for a few days only, after which the increased food intake will itself stimulate metabolism.

Thyroid extract is the only safe stimulant for the premature baby. Brandy appears to be used fairly frequently, but it is irritating to the stomach and intestines and if given in stimulating dosage may produce a dangerous gastro-enteritis. If the baby is kept adequately warm and gently handled brandy should be unnecessary. If anybody needs it, perhaps the doctor and nurse should be considered.

A circular to hospital boards and committees from the Ministry of Health asks hospital management committees to ensure that medical superintendents of mental hospitals and mental deficiency institutions see a copy of all documents on the work of the hospitals and institutions issued to the committee by the Ministry or the Board of Control. It also warns hospital management committees that they should not alter the authorized accommodation in mental hospitals and mental deficiency institutions without the approval of the Ministry of Health.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

QUEEN ADMITTED HONORARY FELLOW

The Queen was admitted an Honorary Fellow of the Royal College of Obstetricians and Gynaecologists on November 3 by Sir William Gilliatt.

Sir William Fletcher Shaw, past President and first Honorary Secretary to the College, and Professor R. W. Johnstone, Senior Fellow in Scotland, presented the Queen for admission.

Sir William Fletcher Shaw said that, as the College had developed and matured and its value to the welfare of the women of the Empire had been more fully established, her Majesty had very graciously become the first Patron of the College. "That your Majesty accepted this office gave great joy to the College and added immensely to its prestige in all the countries of the Empire." More recently her Majesty had shown her great personal interest in the work of the College by the princely gift she had made to its Appeal Fund. "Now by becoming an Honorary Fellow of the College and thus identifying yourself with it in an even more personal way you confer the greatest possible honour on the College."

Professor Johnstone said: "When you, Sir, were kind enough to award me the great and happy privilege of acting as one of her Majesty's sponsors on this occasion, you remarked to me that her Majesty was a Scotswoman and was very proud of it, and that it would be becoming that one of her sponsors should be a Scottish Fellow of the College. In regard to that I would only say that her Majesty's very natural and proper pride of race meets an overflowing complement in the deep and affectionate pride which every Scotsman and Scotswoman the world over takes in her Majesty's most gracious self." All at the College were well aware that the College was receiving a much greater honour than it was giving.

After expressing her gratitude to the College, the Queen said that she shared with all her heart their belief that it was on the happiness of home and family life that the true worth and strength of a nation depended, but what had been so well described as "the miracle of life and the source of all tenderness and love in humanity" demanded more than ever the best technical attention. "It demands a spiritual approach as well, and it is good to know that in your profession its members bring to their work a warm human understanding and a deep sense of moral values."

Handing the Queen her scroll as a Fellow, Sir William Gilliatt said: "May it please your Majesty that I confirm your two sponsors in that the addition of your name will add distinction and lustre to the roll of Honorary Fellows.

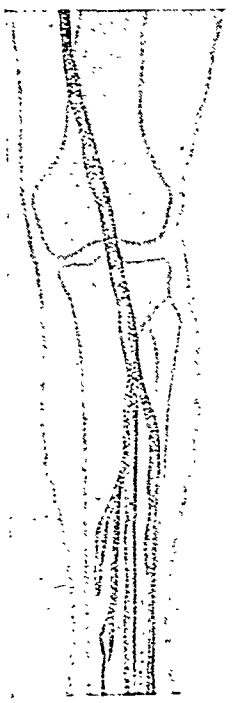
"We are aware that your Majesty has never had, and cannot have, the opportunity of directly advancing the scientific side of our subject. I maintain, nevertheless, that by permitting us to elect you an Honorary Fellow and by your very generous gift to our Appeal Fund you are indirectly advancing in no uncertain manner the important work in which we are engaged. Your gracious acceptance of our Fellowship encourages us to feel that your Majesty is showing an even closer interest in our activities than was possible during the years you have been our Patron.

"We could not have asked you, Madam, to join us did we not consider that there are few higher aims than to contribute to the prevention of illness and the maintenance of health and well-being of mothers and their infants. Your Majesty's sponsors have spoken of the standards of family life in which you have set the world such a wonderful example. In our report on 'A National Maternity Service' published in May, 1944, we use the words, 'We are all conscious that the infusion of higher moral and spiritual values into the families of our country has a profound bearing on physical and mental health.' We on our part are encouraged by your presence here to-day and are determined to show that your trust in our future achievements has not been misplaced.

"May I, on behalf of Council here present and every Fellow and Member, welcome your Majesty as an Honorary Fellow and thank you for your gracious acceptance."

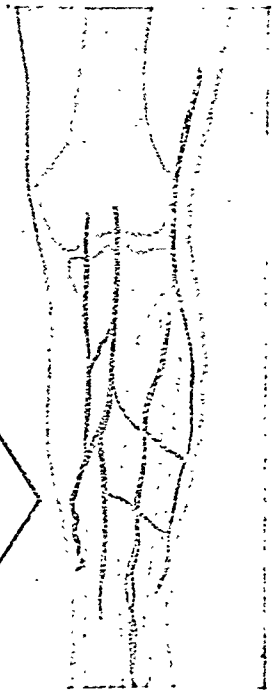
New President Installed

Installing Professor Hilda Lloyd as President, Sir William Gilliatt said that it gave him great pleasure to be the first to congratulate her on assuming the high office to which she had been elected. Her election was an outstanding occasion in that she was the first woman to be elected as President to one of the Royal Medical Colleges. He offered her, on behalf of his colleagues on the Council and for himself, their best wishes for very successful years of office. He wished to record his deep appreciation of her generous action in proposing to and convincing the Council that his term of office should be prolonged so that he might have the privilege of admitting her Majesty to the Honorary Fellowship of the College.



Professor Hilda Lloyd was then vested with the president's gown and repeated the president's oath.

Mr. V. B. Green-Armytage and Mr. J. Eric Stacey were installed as Vice-Presidents in place of Sir William Fletcher Shaw and Mr. James Wyatt, whose term of office had expired.



The Handicapped Pupils and School Health Service Amendment Regulations, No. 2, 1949, make certain interim amendments to the main regulations recommended by the Education Subcommittee of the Local Government Man-power Committee. It is now unnecessary for the local authority to obtain approval of the arrangements made or proposed for carrying on the school health service; the Minister will rely on inspection and on the specified annual returns. The approval of medical officers is limited to those employed in connexion with the authorities' arrangements for ascertaining whether pupils require special educational treatment because of educational subnormality. A number of forms have also been withdrawn because the National Health Service has made them obsolete. Under the Reports to Local Authorities (Records) Amending Regulations, 1949, one of the statutory forms on the reporting of children to the local health authority has been amended to facilitate co-operation between the educational psychologist and the medical officer in order to obviate duplication of work.

HEPARIN (EVANS)

THE PHYSIOLOGICAL ANTICOAGULANT

HEPARIN (EVANS) is indicated in the treatment and prophylaxis of phlebothrombosis, thrombophlebitis and pulmonary embolism. It may also be used to prevent post-operative thrombosis and as an anticoagulant in blood transfusion. Recent work has shown it to be of value in the treatment of coronary thrombosis.

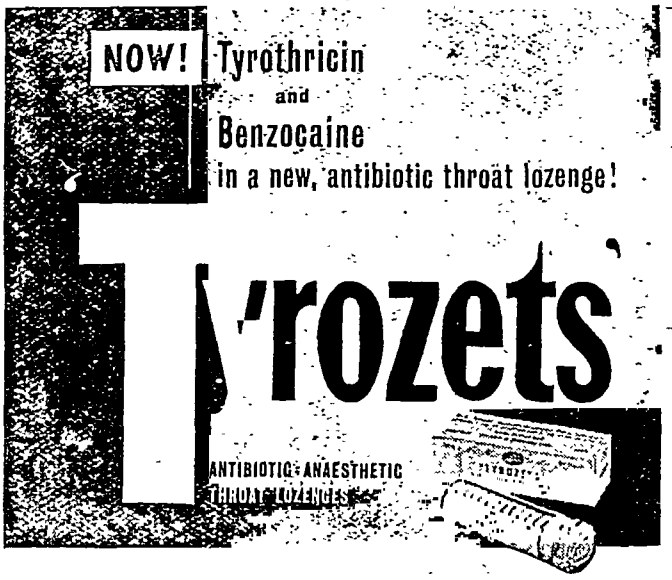
1

2

Two phlebograms showing the radiographic changes in a case of acute thrombosis of the deep veins of the calf.

1) Taken before the onset of symptoms, showing the normal pattern of the deep veins.

2) Taken after establishment of the thrombosis. The deep veins have not filled and the contrast medium has passed over into the large saphenous vein system.



It is now recognised that Heparin given within the first 48 hours of the onset of symptoms will arrest the onward progress of the thrombotic condition in threatened phlebothrombosis of the deep veins of the leg. A total of 250,000 i.u. Heparin given over 7 days will usually bring about remission of all symptoms. Rabinowitch and Pines (1943) working on rabbits, have shown that treatment with Heparin will cause disappearance of an established thrombus in a high percentage of cases by facilitating fibrinolysis by enzymes. There is evidence to show that prolonged heparinisation can be effected by intramuscular injection of the most concentrated preparation. If required the heparin effect can be immediately suspended by the intravenous injection of 5ml. of 1% Protamine Sulphate.

HEPARIN (EVANS) is available in three strengths, each in 5ml. r.c. bottles. 1,000 i.u. per ml: 5,000 i.u. per ml: 25,000 i.u. per ml. *(for intravenous or intramuscular injection).*

PROTAMINE SULPHATE (EVANS) is available as a 1% solution—Boxes of 6 x 5ml. ampoules

Rabinowitch, L. and Pines, B. (1943) *Surgery*, 14, 669.

EVANS MEDICAL SUPPLIES LTD LIVERPOOL AND LONDON

- Pleasantly flavoured and completely stable.
- Exert rapid and prolonged antibacterial action.
- Do not normally cause sensitivity or produce resistant strains of bacteria.
- Effective against organisms usually encountered in oral and pharyngeal infections.
- Rapidly relieve irritation in mouth and throat.
- Provide valuable throat protection when colds are prevalent.
- Issued in vials of 12 lozenges.

GROWTH AND REPRODUCTION OF BACTERIA

Lectures by Sir Paul Fildes

A course of special University of London lectures on general bacteriology was given at University College in October by Sir PAUL FILDES. His account of the growth and reproduction of bacteria covered a wide range, and it is possible to record only certain points of especial interest.

Sir Paul Fildes said that he intended to try to analyse some of the means by which bacteria were maintained as part of the population of the planet. This involved a description of a number of biochemical processes which were not peculiar to bacteria but were common in some degree to all living things. It was hardly possible to lecture on the biological processes of bacteria without making it obvious that bacteria were being used only as illustrations of cellular physiology in general. He might have selected other organisms, such as protozoa or plants or animals, but bacteria were chosen because they were easy to handle and yielded results within a matter of hours. It was for this reason that many of the findings of cellular physiology had been based upon the study of bacteria.

The physiology of bacteria derived its special importance from the likelihood that the control of bacterial activity in health or disease would not be achieved without greater knowledge than was available at present. Bacterial activity became apparent only as a sequel to growth and reproduction. This occurred automatically when conditions were favourable. Growth and reproduction were therefore the prime interests of cellular physiology, because without them the external effects of bacteria for either good or ill would be unimportant.

Organized Enzyme System

It was convenient, Sir Paul continued, to look upon a bacterium not as a mere "bagful of enzymes" but as an organized enzyme system. The organization was such that when the whole system was steeped in the proper substrates the "machine" started to work and continued automatically until the substrates failed or the environment became adverse. The co-ordinated working of the system resulted in an increase in the contents of the bacterial cell until there was a division of the cell into two. When the process was working in full co-ordination—which was not always the case—the time taken by one cell to become two might be some 30 minutes, so that in 24 hours there might be 48 generations and the one bacterium would become 17,000,000.

If nitrogen were taken as the key substance of the protein molecule, it was known from the work of Behring that some bacteria grew in gaseous nitrogen while some grew in such forms of nitrogen as ammonia. As the yield on analysis showed a vast increase in protein, it followed that protein was synthesized from ammonia by the organism. The first thing that happened was that the ammonia diffused into the cell, then it was fixed by one of the receptors of an enzyme and combined with another nutrient fixed by another receptor. In general the synthesis of protein might be looked upon as a chain of reactions carried out by a series of enzymes, each of which had two receptors and two substrates. Eventually by the serial combination of two similar substances the whole protein molecule was constructed.

Genetic Mutations

In order to bring bacteriology into line with general biological teaching it was necessary to make an assumption which could not yet be proved. It was held that the controlling or operating force behind the enzyme was a gene, and that genetic mutations led necessarily to changes in or the disappearance of enzymes in bacteria. These phenomena might have a marked effect on the survival of bacteria in particular environments.

A great deal of work had been carried out in elucidating the manner in which proteins were synthesized, and it was possible to make some tentative guesses at the steps of the synthesis. He described the role of tryptophan as a growth factor, also of indole, which could take the place of tryptophan. It was a question of guessing what two substances might be concerned in the synthesis of indole, for example, and testing whether they would have any effect in the absence of indole. Until an organism could be found which would give a positive growth response to a hypothetical growth factor, guessing could go no further.

The action of a synthetic enzyme was the reverse of that of a degraded enzyme. Energy was absorbed by the former, liberated by the latter. A synthetic enzyme combined two substrates into a larger, while the other type of enzyme split a larger into two smaller substrates. One and the same enzyme was capable of operating in both ways.

In his final lecture Sir Paul Fildes said that it was possible to summarize the two views—the former and the present view—as follows. When the structure of the bacterium altered, whether by the gain or the loss of an enzyme, it was considered to be due to some stimulus deriving from the environment. Broadly, it was said that, if a bacterium found itself in an environment rich in some particular substance which normally it had to synthesize, it did not synthesize and the enzyme associated with the synthesis faded away. The geneticists explained the phenomenon differently. They developed the generalization that behind every enzyme there was a gene which controlled its action. In the course of the reshuffling of genes in the process of cell division accidents might happen, in the same way that accidents might happen in any process which was often repeated. That was merely a matter of statistics. If an accident happened to a gene which affected its normal function the enzyme would be affected. In a normal case with the enzyme present it might disappear, or, if the enzyme was absent from the particular organism being studied, mutation occurred which had nothing to do with environment. The main conflict was whether mutation was merely a matter of chance or was induced by outside causes.

When inoculations in agar without tryptophan were made, a normal typhoid bacillus, for example, did not grow at all at first, but, as the size of the inoculum on the plate continuously increased, the time came when one colony appeared, and more still appeared with further increase of size. If one of these colonies were picked off and tested on the liquid medium it would grow normally and maintain the difference indefinitely. In every culture of typhoid bacilli there were a few abnormal units growing in a different manner. These abnormals were not necessarily present in the original inoculum; they appeared as the culture grew.

Environmental and Accidental Factors

The fact that these mutants made their appearance at widely different points in the growth of the culture, and sometimes not at all, indicated an erratic spontaneous origin rather than the constant influence of the environmental factor. Formerly it was assumed that the environment was concerned mainly with these mutations, but it now seemed reasonably certain that the general idea accepted in genetics held good, that when an operation like cell division was repeated often enough the liability to "accident" increased and there were more likely to be missing or altered genes.

Another series of observations also suggested a genetic origin. It was now well established that exposure of bacteria to constant doses of *x* rays or ultra-violet light caused an increase in the mutation rate of the survivors. This meant that the survivors would produce mutations perhaps at every hundred divisions instead of at every million. The mutants did not occur in the absence of some growth factor. The *x*-ray effect was thought to be due to a filtered chemical action on a single molecule—a one-cell action, the one cell being enough to produce mutation. One of the chief reasons for holding this "one-cell" view was that the number of mutations produced was proportional to the dose of *x* rays.

In sum, therefore, there were reasonable grounds for suggesting that mutations in bacteria and genetic mutations in higher

forms of life had many points in common. They appeared at random and spontaneously, whereas they did not occur following specific changes in the environment. The new character was as stable as the original. In addition to this kind of evidence favouring the existence of genes in bacteria, a more simple argument could be brought forward. No one could imagine that the bacterium was a bag with all its molecules in solution; if this were the case there would be little likelihood of the molecule finding itself on the right side of the curtain when division took place. There must be some mechanism in bacteria as in other cells by which characters were segregated in special divisions.

Sexual Process in Bacteria

It was often supposed that bacteria were non-sexual. Here he recalled an experiment in which a culture of *Bact. coli*, which grew quite well on ammonia because it was able to synthesize all its necessary requirements, was exposed to *x* rays to produce mutants. From the resulting mixture two strains were selected neither of which would grow on ammonia for the reason that one of them was unable to synthesize, say, substances A and B, whereas the other was unable to synthesize substances C and D. Starting with two strains, one of which had lost the genes controlling the A B synthesis and the other the genes controlling the C D, a strain was produced with all the genes and no growth disability. This could have occurred only by the fusion of one cell containing the A B substance with another containing the C D, producing a mutation which contained all four.

The fusion of two cells with reshuffling of the genes was the basis of sexual processes by which hereditary characters were handed on. In animals evolution had produced two entirely separate types of cell, each with complementary genetic disabilities, so that they could not reproduce without fusion. On the other hand, in bacteria this specialization had not taken place. Usually each cell had an adequate genetic establishment, and was developed to allow reproduction by fission in the environment in which it happened to live. At, say, every 20 generations, however, mutations would appear and cells would be produced with different hereditary characters. If two such mutations happened to take place at the same time, and if, more rarely, they happened to fuse and produce a strain of rearranged genetic pattern, and if, finally, this new pattern was more satisfactory for survival in the environment, this would be an established mutation due to sexual process. Necessarily this must be rare. In animals the opportunity existed permanently, and was taken advantage of at short intervals, and for this reason animals had evolved by natural selection more than had bacteria. In general bacteria did not differ, so far as could be judged, from their earliest progenitors.

The argument for including bacteria among the sexed population of the planet was cogent. There could be no doubt that bacterial culture was liable to occasional change in a random manner without any known determining change in the environment. The lecturer pointed out the importance of this in practical work. A bacterial culture could always be looked upon as a population of similar type yet continuously subject to innumerable chance mutations of any of its characters, and any one of those mutations might be selected by the medium which was being used.

The idea of permanent alteration of character resulting from genetic mutation could not yet be correlated with many known facts about bacterial enzymes. In particular, genetic ideas could not be correlated satisfactorily with what was known about the enzymes described as adaptive. Some enzymes had been known to increase in activity or to appear from apparently nothing when brought into contact with a specific substrate, without any cell division at all. This was clearly a phenomenon different from genetic mutation, but it was not a permanent change. It faded away when the substrate was removed, and it was evidently due to environment and not to chance. The vast field for speculation along these lines, as Sir Paul Fildes pointed out in closing his course of lectures, indicated how many matters in the field of bacteriology awaited further research.

Reports of Societies

WHITHER ANTENATAL CARE?

A discussion on this subject took place in the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on October 21, with Dr. LESLIE WILLIAMS presiding. Reference was first made to the election of Professor Hilda Lloyd to the presidency of the Royal College of Obstetricians and Gynaecologists. This was the first time a woman had been elected to the office, and she had gone straight to the position from the presidency of the Section.

Mr. ALECK BOURNE said that to debate the future it was necessary to review the past. The story of antenatal care was a chequered one. Until the middle of the last century no real interest was taken in the examination of the pregnant woman from the point of view of her health. In Great Britain the first clinic for providing supervision and advice for expectant mothers was that established by J. W. Ballantyne in Edinburgh in 1902, but Ballantyne was occupied with the prevention of stillbirths, monsters, and deformities. He was not an obstetrician, and his interest in the health of the pregnant woman was only in so far as it might affect her baby.

The progress of antenatal care was greatly stimulated by the first world war. In 1918 antenatal clinics began to be established, and now there were over 1,600 in the country. They were staffed mostly by antenatal officers who did not conduct the labour. Thus there had been four phases in the progress of antenatal care. The first dated from ancient times. Aristotle's instructions to midwives included such fantastic remedies as the following: "Take a swallow's nest and dissolve in water, strain, and drink it warm, and it gives delivery with great speed and much ease," but there was no mention of the examination of pregnant women. The second was in the latter part of the nineteenth century, when the care of pregnant women from the point of view of eugenics was suggested. The third, associated with Ballantyne, was concerned with the quality of the babies born. The fourth, within his own memory, starting about 1909, was concerned with the discovery of conditions which were likely to make labour difficult. In those days it was uncommon to examine a woman more than twice, towards the end of pregnancy, and no interest was taken in her general health, her personality, or her social surroundings.

This led to an immense amount of interference. Obstetricians became obsessed with the possibility of a difficult labour. If the head was high it was assumed that it would not fit into the brim. G. E. Herman, at the London Hospital, published a book, which was still of great interest and value, entitled *Difficult Labour*, and in the fifth edition (1910) he gave a number of dates from the thirty-sixth week onwards at which induction of labour should be undertaken. Watts Eden published a paper in which he pointed out that the child born from the thirty-sixth to the thirty-ninth week was just as well able to survive as the child born at the fortieth week, and this gave a considerable stimulus to the induction of labour. In Queen Charlotte's Hospital labour was induced in the following percentages of all admissions:

1910	.. 4 per cent.	1920	.. 5.3 per cent.
1912	.. 2.5 „ „	1921	.. 7.4 „ „
1913	.. 5 „ „	1922	.. 6.6 „ „

Between 1928 and 1934 the maternal mortality rate was steadily rising, and in the latter year reached 4.41 per 1,000 live births, the highest figure since the 'nineties of the last century, and this after 15 years of increasing antenatal care and improved teaching of students and midwives. It was not surprising that critics began to point out that antenatal care had failed in its object of reducing the death rate in child-bearing. It was gradually realized that external measurements were useless, but unfortunately the mechanists had another lease of life as a result of *x*-ray pelvimetry.

Throughout the whole range of medicine, Mr. Bourne continued, there was a tendency to confine the supposed normal within too narrow limits, and this was more marked in obstetrical

work than in any other branch. One example was the use of pelvic measurements in the prognosis of labour. Even with reduced measurements there might be a difficult labour only if the uterine contractions were feeble; there were few complications which did not lose something of their potential danger if the uterus reacted strongly. If function was so important, was it possible to predict it during pregnancy, and, if it was, could anything be done antenatally to ensure the maximum possible function? In many cases he thought this could be done. He believed that the function of the uterus depended primarily on the emotional attitude of the woman in labour, chiefly her degree of anxiety. It depended also upon her clinical or biological type. The vast majority of women could not be divided into one or other of the extreme types—the functionally good reproductive type and the difficult type—but it was possible with insight and experience to say on which side of the middle line they were.

The function of the uterus could be predicted by watching the emotional attitude of the woman to her forthcoming labour. Many began their pregnancy in ignorance and went through it in uncertainty and fear, and their fear was such that it was practically certain they would have inertia, maximum pain, and an assisted delivery. Antenatal visits afforded an opportunity for watching the state of mind and understanding the emotional state. Sometimes the condition was masked by a spurious courage, but it was possible to break that down and see what lay underneath. Nothing could be done to alter things physically, but a great deal could be done to exorcise fear and liberate uterine function from the inhibitions which fear imposed upon it.

On the question of diet, Mr. Bourne suggested that there was no evidence as yet that malnutrition had an effect upon uterine contraction, though it certainly had in precipitating early labour. As for exercise, its chief value was in making the woman feel that she was contributing something to the preparation for her labour.

Elimination of Fear

Professor W. C. W. NIXON said that he was a student of Mr. Bourne's a quarter of a century ago, and recalled his teaching on the necessity for a shift of emphasis from structure to function. Unfortunately, the mechanistic fog still existed, but there was an awakening to the need for taking the woman as a whole, considering both *psyche* and *soma*. The normal pregnancy had not the drama of the abnormal, and the assistant and student gaining experience voted a week without an incident as rather dull.

In his opinion there should be a food advice bureau attached to every antenatal clinic. Nutritional anaemia was still prevalent, and the only way to detect it was by an estimation of the haemoglobin. Every pregnant woman should have her haemoglobin estimated on her first visit and again at the thirty-sixth week. Investigations had shown that the idea that excessive weight was an indication of toxaemia was a fallacy. During the last few years at the antenatal clinic at University College Hospital radiography of the chest had been done as a routine, and the results had justified the procedure.

At University College Hospital it was felt that by the introduction of training classes much had been done to eliminate fear. In these classes the changes in pregnancy and the birth process were explained, and the mother was given confidence and enabled to recognize the various events of labour as signposts rather than as hidden enemies. It was Dr. Grantly Dick Read who had first pointed out the importance of the tensions set up by fear and how these could be relieved by reassurance and relaxation. Everyone recognized the need for mothers to be physically fit so that they could pass through labour relatively unharmed. It was important also to prevent mental trauma. If this were neglected the mother was denied an enriching and satisfying experience.

Professor Nixon then showed a film, taken in his out-patient department, illustrating the type of physical exercises taught to expectant mothers, and also the work of the food advice bureau. The film had been specially prepared for the meeting by Mr. P. L. C. Diggory, film secretary of the British Medical Students Association.

Value of Exercises

Mr. A. P. WRIGLEY said that at long last the general health of the patient was receiving attention. Energetic measures had been adopted to prepare the mother physically and mentally for labour, the physical side being dealt with by remedial exercises, proper food, and teaching of correct stance and relaxation. The first results were beginning to come in and were not as encouraging as might have been hoped. The statistical difference between patients who had had exercises and patients who had not did not appear to be marked. In a further attempt to help patients at St. Thomas's physiotherapy had been combined with a mild form of psychotherapy, but an analysis of 106 women who had elected to join these classes, when compared with a number of controls, seemed to show no advantage. No one regretted this more than he did, although the sister told him that these patients were in a much happier frame of mind when they arrived for labour. He had no doubt that this work was in its infancy, and would show better results as experience accumulated.

He thought there should be a much more common-sense outlook about the expected date of delivery, and less, not more, attention should be given to the pre-natal preparation of the patient for breast-feeding. If on a casual observation the breasts appeared normal and the woman accepted breast-feeding as the natural thing, he regarded any treatment of the skin or massage of the breast as unnecessary and undesirable. The position with regard to *x*-ray examination had changed during the last ten years as a result of intensive and painstaking observations. The technique of radiology was now such that risks of misinterpretation had decreased. The day was not far distant when an *x*-ray picture would be made of the pelvis of every woman embarking on her first pregnancy, and this would be done by someone trained for that work.

He pleaded also for a less rigid adherence to routine—routine in attendance or in the procedure at the clinics. Patients differed from one another right down to the last weeks of pregnancy. The lives of patients had become so regimented that if the burden could be eased by less adherence to schedule and more use of common sense it was the doctor's duty so to ease it. Finally he spoke of the liaison between outside antenatal clinics and those who had the care of labour. Instead of drawing them nearer, the effect of recent legislation was to drive them further apart, and as long as the present system continued the care of the woman remained divided. Altogether, while the results of the last 15 years had been good, he was certain they could do better.

In some brief general discussion Dr. ARNOLD WALKER said that he thought there should be a little less criticism of what the local authorities had done in the antenatal clinics, for, after all, this was the only way in which many women could get antenatal care, and the closing of many such clinics created a gap which it would be difficult to fill. Another speaker pointed out that, whereas at the hospital clinics there was no guarantee that the patient would see the same doctor again, at the local authority clinics the people worked as a team and also had a broader outlook on the background of social medicine than their colleagues in hospital. Dr. HAROLD WALLER said that mastitis was almost a preventable disease, but in some clinics it was as high as 10% among lactating women

Mr. ALECK BOURNE, replying, said that he wondered whether it was possible to relate the benefit of antenatal physical exercises to a statistical presentation of abnormalities at labour One value of the exercises was to give a woman a positive attitude towards her own effort.

HYPOPITUITARISM

At a meeting of the Liverpool Medical Institution on October 13, with the president, Professor Charles Wells, in the chair, Dr. V. K. SUMMERS read a paper on the syndrome of hypopituitarism.

Dr. Summers said that the commonest cause of severe chronic hypopituitarism was necrosis of the anterior lobe at the time of delivery. These patients were in a state of severe circulatory collapse, and this collapse was produced usually by a

combination of shock and haemorrhage; the obstetric conditions likely to be associated with pituitary necrosis were postpartum haemorrhage and retained placenta. The symptoms and signs were due to a failure of secretion of pituitary hormone. The first sign was failure of lactation, and in these cases no milk could be expressed.

Nutrition was unimpaired in these women, and the majority were, if anything, slightly above average weight for their height and age. The term "pituitary cachexia" used for this syndrome should be abandoned, because it was misleading and the source of many errors in diagnosis. Failure of menstruation with severe atrophy of the whole of the genital tract was an invariable sign.

Signs of adrenal insufficiency were constant; electrolyte changes which resembled those of Addison's disease, but of less severe degree, occurred. In contrast to the heavy deposition of pigment in Addison's disease, a depigmentation of exposed areas of the body and of normally pigmented areas—for example, the areolae—was seen in hypopituitarism. Loss of pubic and axillary hair was always noted within two years of the onset of the disease. The excretion of ketosteroids was reduced to very low levels. Loss of thyreotropic hormone secretion produced symptoms like those of hypothyroidism: a dry skin, low basal metabolic rate, elevated blood cholesterol, sensitivity to cold, and cardiac changes resembling those of myxoedema. Cardiac enlargement did not appear, and the scalp hair remained normal in amount and texture.

Professor H. L. SHEEHAN said that the anterior lobe of the pituitary could be destroyed by a variety of pathological lesions. The most important of these was post-partum necrosis, which accounted for about three-quarters of the cases of severe destruction of the gland. The loss of anterior lobe hormones produced a great atrophy of the adrenal cortex, the thyroid, and the gonads, and the loss of hormones from the gonads led to atrophy of the genital tract.

Dr. C. O. STALLYBRASS referred to the work of Dougherty and White on the activity of the adrenotropic hormone in stimulating the mechanism of antibody production and, more especially, lymphocyte and plasma cell destruction with consequent liberation of antibody. If the adrenal cortex was gravely affected, as in the Friedrichsen-Waterhouse syndrome in meningococcosis, then a twofold lethal effect would be produced. He also referred to veterinary interest, described by Kay, in the action of the lactogenic hormone in assisting cows to "let down" their milk, and the experiments that had shown that while the stimulus might be neural the mechanism was hormonal.

Nova et Vetera

DISCOVERERS FOR MEDICINE

Discoverers for Medicine. By William H. Woglom, M.D. (Pp. 229; illustrated. 18s.) London: Geoffrey Cumberlege. 1949.

The purpose of this unusual book is given in the author's quotation from Oliver Wendell Holmes—"Medicine learned from a Jesuit how to cure ague, from a friar how to cut for stone, from a soldier how to treat gout, from a sailor how to keep off scurvy, from a postmaster how to sound the Eustachian tube, from a dairymaid how to prevent smallpox, and from an old market woman how to catch the itch insect." The author describes these and many other debts which our profession and its patients owe to the traditions and common sense of the unlearned and to the patient researches of scientists whose work and results seemed to have no bearing on medicine. With an easy style and infinite patience Dr. Woglom traces to these sources the benefits of vaccination, of digitalis, of quinine, of spectacles, and of many other aids and remedies which we now take for granted without a thought for their obscure beginnings. The book is handsomely produced, with many good illustrations and a copious bibliography and index. In illuminating the background of his discoverers the author does so with vivid sketches of the personalities of his heroes. ALFRED COX.

Correspondence

British Branch of Ligue Internationale Contre le Rhumatisme

SIR,—The recent International Congress on Rheumatic Diseases in New York at which Hench and Kendall presented their paper on "cortisone" was sponsored by the Ligue Internationale Contre le Rhumatisme, and there can be no doubt in the minds of those who heard this paper and availed themselves of the varied opportunities at this congress of the immense value of such meetings.

We feel that the British Branch of the Ligue is not sufficiently widely known and that membership offers not only individual advantages but an opportunity to foster friendly international relations at these various gatherings held in different countries. The next congress of the Ligue Européenne is in Barcelona in 1951, and the whole Ligue Internationale will meet in Zurich in 1953. Judging by the high standard of papers in New York this year, these two promise to be important meetings.

Individual membership of the British Branch entitles attendance at these congresses and also at certain clinical meetings of the Heberden Society. The British Branch is arranging a quarterly publication of a pamphlet giving news of forthcoming meetings of interest, of postgraduate courses, and a list of clinics where postgraduate members will be welcome.

The annual subscription is one guinea and should be sent to the treasurer, Dr. G. D. Kersley, 6, The Circus, Bath.—We are, etc.,

London, W.C.1.

W. S. C. COPEMAN,
President, Ligue Européenne.
OSWALD SAVAGE,
Secretary, British Branch of the Ligue Internationale Contre le Rhumatisme

Progress in Obstetrics

SIR,—Since you did me the unexpected honour of using some of the subject matter of my Joseph Price Oration in America and my presidential address to the Edinburgh Obstetrical Society as a sort of text for your leading article on "Progress in Obstetrics" (October 8, p. 799), I feel it is incumbent on me to take some part in the discussion that has followed.

I am almost in entire agreement with the views advanced by Professor Andrew M. Claye (October 22, p. 927), which vary little from the suggestions I advocated in my Edinburgh paper. There is little doubt that the teaching of obstetrics has advanced greatly during the last twenty years, and, as I pointed out, I considered that this was one of the several reasons which had helped to lower the maternal mortality and morbidity. But even now, in my opinion, the newly qualified graduate is seldom capable of undertaking midwifery in a general practice until he has acquired more experience. This is not due to the teachers of obstetrics or to the students themselves, but to the paucity of cases available to give each student a thorough grounding in such everyday procedures as forceps delivery, the suture of the torn perineum, episiotomy, etc., not to mention the more difficult manœuvres, such as the turning of the occipito-posterior, external version for a breech presentation in a primipara, etc. It would therefore seem to be necessary to conserve cases for those who desire to practise midwifery in their general practice, and not to provide a number of midwifery cases to those who are later not going to be general practitioners but surgeons, pathologists, bacteriologists, psychiatrists, etc.

I suggested that if a year was to be spent following the final examination for clinical work before a degree was conferred those hoping to practise midwifery in the future would spend at least three months resident in a maternity hospital, where they would get an opportunity of carrying out the procedures I have already mentioned and at the same time obtain further clinical experience in normal and abnormal midwifery. In order to make cases available I suggested that it might be quite sufficient for the ordinary undergraduate to attend five

IN BRONCHIAL ASTHMA

1600: "*The specifics commonly used for moist asthmas are the roots of Cuckowpint, Hyssop, Horehound . . . . the syrup or volatile salt of Tobacco; Gum Ammoniac (above all) dissolved in vinegar. Compound Spirit of Verdigrise, dulcify'd Spirit of Nitre, Turpentine . . . . Balsam of Sulphur . . . . Juice of Woodlice with wine (an incomparable medicine) and the carminative spirit if the stomach be disordered.*" MICHAEL ETMULLER, *Professor of Physic, Leipzig*

Today: The "incomparable medicine" in bronchial asthma is 'Neo-Epinine.' Patients obtain relief without the discomfort of repeated injections, the side-effects of adrenaline, or the sleeplessness of ephedrine medication. 'Neo-Epinine' is administered sublingually as a compressed product or by oral inhalation as Spray Solution,

'NEO-EPININE'

ISOPRENALINE SULPHATE

BURROUGHS WELLCOME & CO. (*The Wellcome Foundation Ltd.*) LONDON

LAWS OF MEDICINE

Bell's Law

"The anterior roots of the spinal nerves are motor, and the posterior roots are sensory"

This illustration, drawn by Bell himself, is taken from his book on the study of nerves, published in 1816. SIR CHARLES BELL *(1774-1842) was equally eminent as a surgeon and an anatomist. He was Surgeon to the Middlesex Hospital from 1815 until 1835, when he was appointed to the Chair of Surgery in Edinburgh.*

TO BELL and other great pioneers of the nineteenth century, we owe the beginning of modern knowledge of anatomy and physiology. More recent and even more spectacular is the advance attained in therapeutics since the introduction of synthetic compounds.

In this and every other branch of drug manufacture, the Boots organisation is constantly active to meet the needs of modern therapy. Behind its great resources for research and production there is a long tradition of service to the medical profession.

Concessionary Offer

TO MEMBERS OF THE MEDICAL PROFESSION

ELECTRIC WARMING PADS AND BLANKETS

THERMOSTATICALLY CONTROLLED
FULLY GUARANTEED FOR ONE YEAR

DENHAMS (NCH) LTD., makers of Norvic Electric Warming Pads and Blankets, take pleasure in announcing that they are able to repeat their last season's Concessionary Offer to Members of the Medical Profession at even more advantageous prices:

NORVIC

Single-Heat Pads	32/6
Multi-Heat Pads	44/6
Single-Heat Blankets ...	87/6
Multi-Heat Blankets	105/-

All prices include P. Tax and free delivery by Registered Parcel Post.

To assist in prompt execution of your order please write name and address clearly in block letters.

★ **Please note that the above offer only applies if order is passed directly to the makers**

Illustrated leaflet on application

normal cases during his obstetric course and that residential stay in a hostel attached to the maternity hospital to study abnormal midwifery would be unnecessary. This would give the G.P. obstetrician-to-be much more material wherewith to acquire a better knowledge of the subject, and hostel accommodation in or near a maternity hospital would be available. Accommodation and the required tuition could be supplied not only in the present teaching hospitals but in non-teaching hospitals all over the country as well, on whose staff there was an obstetrician qualified to teach such students. A practitioner who had not previously taken this extra instruction and who wished later to do midwifery could take such a course at any time. In order to know which doctors were suitably qualified a diploma, such as D.Obst., might be given at the end of each course to all those who had acquitted themselves to the satisfaction of the consultant in charge, or after passing a small clinical examination conducted by an outside panel of examiners.

I quite agree with Dr. Walter Radcliffe (October 22, p. 927) that permission should be granted to general-practitioner obstetricians to attend patients in a number of maternity hospitals in the country provided they obey the rules of the hospital concerned and their work is supervised by the consultant in charge in the same manner as all the rest of the cases in the hospital are. This plan is carried out in a large number of the maternity hospitals in the U.S.A. with most satisfactory results, the practitioners being on what is called the "courtesy staff," and I may state that such facilities are already accorded to practitioners by at least one regional board in this country.—I am, etc.,

Edinburgh. W. F. THEODORE HAULTAIN.

Natural History of Asthma

SIR,—It is a long time since I practised medicine and I should not dream of criticizing the article by Drs. Elsie O. Williams and G. E. O. Williams (October 22, p. 897). At the same time, I cannot help feeling that it falls short, in some ways, of its majestic title.

My late friend, James Adam, of Glasgow, was interested in the subject precisely from the point of view of "natural history" and I doubt if he would have approved an essay which took so little account of habit and environment. In his search for clinical findings, too, he was more fortunate than your contributors. For example, he found eosinophilia almost universal and a consistent lowering of the systolic pressure. He attached much significance to these findings, and thought that the main factor was metabolic. It is perhaps a pity that this line of inquiry appears to have been dropped.—I am, etc.,

Helensburgh, Dumbarton. O. H. MAVOR.

SIR,—In their researches into the natural history of asthma Drs. Elsie O. Williams and G. E. O. Williams (October 22, p. 897) have presented a number of points and conclusions which lend support to the findings of other investigators, but at the same time have formed conclusions which might be regarded as highly controversial. In particular I would like to refer to the "relevance of hormonal allergy in women."

Few will dispute the increased incidence of asthma at puberty, and it may be significant that many become asthmatic for the first time at that period. In the same way the condition may appear initially or become aggravated during pregnancy. But, as stated in your annotation (October 22, p. 921), many are relieved of their distress when pregnant—a fact which is difficult to reconcile with the authors' theory. Important in this connexion is the finding of Kapeller-Adler[1] that the histamine values in the blood cells of pregnant women were comparable in amount with those of non-pregnant women. That positive skin reactions to endocrine hormones have been obtained is neither surprising nor convincing seeing that the results of skin testing are to be considered suspect rather than unequivocal evidence of allergic sensitivity.

Is not the reason for the greater frequency at puberty and in some pregnancies to be found, as has been suggested in the past, in the alteration of the mode of life of the adult woman as compared with the adult man? For at that time woman adopts a much more sedentary type of existence, with consequent slowing of metabolism and reduction of the stimulating effects of weather—influences which tend to encourage parasympathetic preponderances. The relative infrequency of asthma in the more primitive races supports this point of view. Certainly the encouragement in these girls of a more spartan type of existence is in itself frequently sufficient to ameliorate the illness to a very considerable degree. The question arises once again whether there is some intimate relationship between the increase of allergy and the increasing artificiality of our existence.—I am, etc.,

Glasgow. GEORGE KRASNER.

"Mantoux-conversion"

SIR,—There is a place in the English language for a term to indicate a change from the tuberculin-negative state to the tuberculin-positive state, but the use of two different terms with this meaning leads to confusion. In the American and English literature the term "Mantoux-conversion" is used to indicate this change, but some Scandinavian writers have preferred the term "Mantoux-inversion," and recently one English writer has followed them.[1] To the ordinary English reader "conversion" clearly indicates a change from a first state to a newly acquired one, while "reversion" equally clearly indicates a change from an acquired state to a pre-existing one. "Inversion" suggests merely a "turning upside down," with no implication as to the nature of the change.

For the sake of clarity and uniformity, therefore, it would be preferable for all writers on tuberculosis to use "Mantoux-conversion" to indicate the change from the tuberculin-negative to the tuberculin-positive state, as shown by the Mantoux technique. Mantoux-reversion is the correct term to indicate the change from tuberculin-positive to tuberculin-negative. I am sure that our Scandinavian friends, who have such a remarkable and enviable command of our language, will be willing to drop the term "Mantoux-inversion," which has no real etymological justification for use in the sense it has acquired.—I am, etc.,

London, W.1. CHARLES NEWMAN,
Chairman, Prophit Tuberculosis Survey Committee, R.C.P.

Myxoedematous Madness

SIR,—Surely it is time that the science of semantics and the art of logical reasoning were taught in our medical schools. I can read no alteration of opinion in Dr. Richard Asher's letter (October 8, p. 818), yet Dr. E. B. Davies (October 29, p. 982) writes as if such an alteration had been expressed. This is not scientific discussion but misrepresentation, which is fortunately not common in science.

"Mad" is a term used by the laity for behaviour which varies from the mean so far as to endanger the subject or his fellows; it excludes delirium, in which the patient appears physically ill. Dr. Asher used the term correctly in the title of his article, most of his patients being referred to hospital by an authorized officer—a layman—because their behaviour was grossly abnormal and they were not delirious. Dr. Asher's task was to assess the degree of abnormality, and, if his observations confirmed those of the authorized officer, to discover whether there was physical disease associated with the disordered behaviour. He was successful, and restored nine patients to physical health and normal behaviour. The relation between physical disease and abnormal behaviour appears to be that of cause and effect, for reasons explained in detail by Dr. Asher; they are perfectly logical reasons and suffice to establish a reasonable presumption that this hypothesis is true.

The term psychotic is being used in two senses: first, as equivalent to "mad"—as in the term "organic psychosis"; and second, as a technical term used in psychology. The first use includes states varying from "clouding of consciousness"

to catatonia, but the second is much more selective: many psychotic patients can earn a good living.

"Mad" patients with gross disorders of behaviour may be suffering from organic disease or from some disorder without discoverable organic cause. Most people know that an acute psychosis can develop apparently as a response to a severe emotional stress, but it is equally important to recognize that madness may result from organic disease. G.P.I., myxoedema, or epileptic equivalents may all appear in the observation ward, and, as far as I know, the response to treatment of the organic disease is at least as satisfactory as is that to psychotherapy.—I am, etc.,

Teddington, Middlesex. GEORGE DISCOMBE.

SIR,—In the interesting article by Dr. R. Asher on myxoedematous madness (September 10, p. 555) and in the annotation (p. 587) the often missed diagnosis of hypothyroidism is pointed out. In the list of signs that help the practitioner to establish a right diagnosis the presence of myoidema is omitted. However, in my experience the presence of a marked myoidema after mechanical stimulation of skeletal muscle is of significant practical value, since its absence virtually eliminates the diagnosis of hypothyroidism.

The localized muscular contraction that determines the erroneously called myoidema is observed in several conditions, generally accompanying a negative balance of nitrogen, but never reaches the proportions and specially never lasts so long as in myxoedema. Furthermore, the disappearance of the phenomenon after thyroid treatment indicates the direct relation between the abnormal muscular response and the endocrine disturbance. On the other hand, the rare and fleeting myoidema that is observed in hyperthyroidism is another evidence of the effect of thyroid gland upon the reaction of skeletal muscle, since in this condition, with its muscle wasting, a marked myoidema would be logical to assume.

This important sign was first observed in hypothyroidism and myxoedema by Södebergh,[1] who gave a right explanation of it. Recently, apropos of a study of skeletal muscle in hypothyroid conditions, I insisted on the practical value of this sign, which goes hand in hand with the results of the treatment.[2] It is objective and does not depend on the good will of the patient. It should be remembered that in patients with marked infiltration of subcutaneous tissue it is better to palpate the biceps than to look at it after vigorous pinching of the muscle, the better form of applying a mechanical stimulation. In other rare conditions not entirely due to a deficiency of the thyroid gland but undoubtedly connected with it—such as hypertrophia musculorum vera and the syndrome of Debré-Semelaigne—myoidema assumes enormous proportions.—I am, etc.,

SIR,—I have always been struck by the way that opposing correspondents misunderstand each other's views. The correspondence about my article on myxoedematous madness (September 10, p. 555) seems no exception. Dr. E. B. Davies (October 29, p. 982) is pleased that I no longer hold my "unrestrained opinions," but in my letter (October 8, p. 818) I did not alter them, I only explained them again. I regard myxoedema as an important cause of insanity because it is important for people to know about it, because it is important to recognize and treat it, and because it is not rare and may often be rapidly cured.

I cannot quite understand why Dr. H. Bourne (October 29, p. 982) wishes to discount six of my cases because they had on occasion clouded consciousness. Their madness was due to the myxoedema just the same, and it certainly did not (as Dr. Bourne says) "respond to thyroid as they regained consciousness." Case 5 became so irrational that she upset the whole of the ward, and Case 10 became maniacal and hallucinated for over a fortnight (this is made quite clear in my paper). Of the three which he says failed to respond, two showed considerable improvement (again quite clear in the paper).

Dr. Bourne says it requires more evidence to show that myxoedematous madness is a more distinct entity than "rheumatic madness," "acute haemorrhagic madness," etc. The evidence (apart from these 14 cases) is to be found on page 31 of the report by the Clinical Society of London[1] and in all the other references given at the end of my article, whereas there is nothing known about rheumatic madness or acute haemorrhagic madness. Further evidence is supplied by letters and messages I have had from doctors who have met similar mental changes with myxoedema and also by two more cases I have seen since I wrote the article.—I am, etc.,

London, W.1. RICHARD ASHER.

*** This correspondence is now closed.—ED., *B.M.J.*

Splenic Puncture

SIR,—Though sternal puncture has become an indispensable procedure in the study of the blood cells, in temperate zones diagnostic puncture of the spleen is becoming more frequently used. Splenic puncture is particularly helpful in the study of the cells of the lymphatic and reticulo-endothelial series and in the diagnosis of the obscure leukaemias and reticuloses. In the Tropics spleen puncture is much more frequently performed, especially for the diagnosis of kala-azar. Recently, however, splenic puncture has tended to become replaced by sternal puncture because of the supposed danger of the former and because in kala-azar the latter is supposed to give as many positive smears.

There is little justification for either of these suppositions. Although occasional deaths are reported as the result of spleen puncture, those with the greatest experience of the procedure find it perfectly safe.[1–3] Debono[4] in his experience of 2,000 cases of infantile kala-azar had only two deaths—one in a case of leukaemia and one in a moribund patient. Chung[5] reported 50 cases of kala-azar in which spleen smears gave fewer positives than either lymphatic gland or sternal smears, but in recent years he has seen cases in which sternal smears were negative and spleen smears positive (personal communication). Napier[6] in one series of 55 cases found 9 positive spleen smears in 11 cases with negative sternal smears. In another series[2] he found 9 out of 80 cases to have negative sternal smears; six of these nine patients were examined by spleen puncture, and positive smears were obtained in three. The writer has never found parasites in sternal smears when they were absent from spleen smears. The only large-scale comparative study is that of Ho and his colleagues,[7] who examined smears from both spleen and sternal punctures in each of 450 cases of kala-azar. They found sternal smears positive in 85.8%, while spleen smears showed leishmania in 97.6%. Napier and Ho agree that when parasites are present in both sternal and spleen smears they are easier to find in the latter.

During the past 18 months the writer has been using a simplified technique of spleen puncture the safety of which is demonstrated by the absence of mishaps in nearly 1,500 punctures, one-third of these being on cases of splenomegaly from causes other than kala-azar. The advantages of the technique are not only its safety and simplicity but also its rapidity and the fact that it can be carried out in every case regardless of the presence of blood changes. It requires no co-operation from the patient and can be used in infants and children, crying, struggling, or otherwise. Patients need no preparation or local anaesthetic, and they get up immediately after the puncture. The procedure may be repeated as necessary. The technique is as follows.

A dry all-glass 10-ml. syringe is used with a 22-gauge needle (1¼ in. = 3.1 cm.). The plunger of the syringe must be well fitting but freely movable within the barrel, and with the needle attached the syringe should be tested for these points just prior to performing the operation. The patient lies flat on a bed, and the skin over the spleen is cleaned with alcohol and allowed to dry. The operator stands on the patient's right side and with his left hand palpates the edge of the spleen. The right hand inserts the needle under the skin about midway between spleen edge and costal margin. The left hand then takes the barrel of the syringe and the right thumb and forefinger take the head of the plunger. With a rapid movement of the left hand the needle is thrust for a depth of about 1 cm.

into the spleen and immediately withdrawn from the patient. At the same time that the left hand pushes the needle into the spleen the right hand forcibly withdraws the plunger, so that during the fraction of the second that the needle point is within the spleen a partial vacuum is produced within the barrel. (The needle penetrates the splenic capsule at an angle of about 75° to its surface, though, since there is no time for the spleen to move while the needle is within its substance, this angle is unimportant.) Enough material is obtained on the tip of the nozzle of the syringe or within the needle for the making of a smear.

A similar technique has been used for liver puncture and for puncture of spleens which are not palpable. In the latter case the position of the organ is determined by percussion and the needle thrust between the ribs. Before using this technique, the rapid, co-ordinated movements of the hands should be practised.—I am, etc.,

Brighton. EMANUEL TUCKMAN,
Director, Anti-kala-azar Campaign, Friends' Service Unit (China).

Lymphadenopathy in Brucellosis

SIR,—Dr. Hugh Conway's interesting article on lymphadenopathy in brucellosis (October 8, p. 787) was of great personal interest to me in view of the extensive work on the subject of Malta fever carried out by my father, the late Colonel J. C. Kennedy. He served in Malta from 1901–6, and was appointed a member of the Malta Fever Commission on its formation in 1904. In 1908 he received the Edinburgh University Gold Medal for his M.D. thesis on Malta fever. Parts I and III of this thesis deal with the aetiology, epidemiology, immunity, and prophylaxis of Malta fever, while part II is a description of the clinical conditions based on the personal observation of 250 cases. The following paraphrased extracts from this thesis seem to have some bearing on the question whether or not lymphadenopathy occurring in a patient with *brucellosis* is a specific manifestation of the disease.

1. In the section dealing with aetiology and experimental pathology the following findings are recorded. The experimental inoculation of *M. melitensis* into a monkey and two dogs caused enlargement of the spleen and certain lymph glands 20–60 days after the inoculation. *M. melitensis* was recovered (in profusion) from the mesenteric, femoral and axillary glands in the case of the monkey, and from the inguinal and axillary glands in the case of the two dogs.

2. Under the description of symptoms by systems is the following paragraph. "All the lymphatic glands are slightly enlarged, and those lying in the neck posterior to the sternomastoid muscle become tender very early in the disease. The glands are the last organs on the body for the micrococcus to leave (see morbid anatomy). Lymphangitis has occurred in one case in both legs with enlargement of the popliteal glands."

3. The following paragraph occurs under the heading "Post-mortem Bacteriology." "The organism *M. melitensis*, is recovered from the following organs in the greatest profusion in order of precedence: lymphatic glands (when fluctuating), spleen, liver, bone marrow, kidney. The observation that the lymphatic glands were so favourable to the recovery of the organism (Kennedy, *Malta Fever Reports*, IV) was of the greatest value from an experimental point of view, as it was proved that the organism remains in these organs long after it has disappeared from all other parts of the body. Therefore it became routine practice when making post-mortem examinations on experimental animals to make cultures from several of the glands. In many cases it was the saving of the experiment when these organs were the only ones containing the micrococcus."

In 1906, as a result of the findings of the Malta Fever Commission, the consumption of unpasteurized goats' milk was prohibited to all British Service personnel. Prior to that date the average incidence of Malta fever in the Malta garrison alone was in the region of 600 cases yearly. Since 1906 the incidence of Malta fever in the garrison has for the most part been only sporadic. For this reason it is probable that there will never again be such a wealth of material available for investigation and analysis. It is on these grounds that I submit the above extracts.

It may interest your readers to know that it was Colonel J. C. Kennedy who in January, 1914, provided the first clue that cows' milk might produce undulant fever in humans when he reported the presence of agglutinins for the *Micrococcus melitensis* in the milk and blood serum of cows in London.[1] Unfortunately, due to being posted overseas, he was unable to follow up this observation. It was four years later, in 1918, that Miss Alice Evans showed that these agglutinins found in the milk and blood serum of cows were due to infection by the closely allied *Brucella abortus*.—I am, etc.,

Penarth, Glam. M. C. S. KENNEDY.

Tetraethylthiuramdisulphide in the Treatment of Alcoholics

SIR,—I am glad that Dr. J. N. P. Moore (October 22, p. 932) has drawn attention to the need for a careful technique in the exhibition of this new drug. In answering the many inquiries I have had regarding it I have never failed to stress the importance of a proper selection of patients and control of conditions. Dr. Moore does not, I think, realize that no patients are accepted at Caldecote unless they promise, with their lips at any rate, to co-operate whole-heartedly during whatever course of treatment is prescribed for them. They are warned that any surreptitious consumption of alcohol while they are under treatment and on parole is liable to bring upon them distress up to the point of danger. Actually I never have encountered a dangerous state, though laymen, seeing a man as red as a turkey-cock and in the throes of acute anxiety, have told me *with alarm that he seemed to be in extremis* and "about to pass out." Some patients to whom I do not wish to give the drug I invite to act as umpires while a more robust fellow is undergoing test. They finally conduct the latter to bed and declare that a personal experience is not necessary for them; the vicarious atonement suffices. Quite possibly there exist individuals allergic to tetraethylthiuramdisulphide just as there are those allergic to other substances—e.g., strawberries, belladonna, bee-stings, etc.—but such have not crossed my path, or I intuitively have passed them over. Dr. Moore does not refer to the interesting fact that if a resistant patient on a small regular dose of the drug manages also to take a small quantity of alcohol he develops as the days go by, in addition to a pink complexion shortly after drinking, peripheral neuritis and mild general confusion. I have known several such cases and deliberately let them continue in order to observe results.

As to giving the drug for a few months only—this is just to help a patient by affording initial confidence and a sense of security while he is facing life again after a course of general and psychotherapeutic treatment. The drug alone cannot effect a cure; it only can act as a useful ancillary to a psychological reorientation of the character defect which in the first instance induced the individual to try to bolster himself up by recourse to alcohol. No drug of itself ever cures addiction. Unless the personality is readjusted relapse ensues when and if, sooner or later, fate turns on the screw appropriate to elicit that individual's malreaction, whatever it be.

The value of your space precludes me from entering into a more detailed exposition of this thesis. I conclude with the caution that to exploit any drug, new or old, with the promise that it will suffice to make a person behave himself for what politicians call "all time" is worthy of condemnation as quackery, be it consciously or ignorantly pursued.—I am, etc.,

Nuneaton. A. E. CARVER.

The Artificial Kidney

SIR,—With reference to letters and articles on the renal shunt and the artificial kidney I beg to suggest a much less drastic procedure to deal with anuria. In 1906 and 1907 I performed my first experiments with diathermy at the Veterinary Institute of the University of Berlin. After exposing by laparotomy both kidneys of rabbits or dogs and then treating one kidney from the back through all the integuments I noticed that the treated kidney assumed after a minute or two a highly arterial coloration while the other kidney remained bluish. I explained this effect by the local spasmolytic action of diathermy and

consequently used it as a life-saving device in cases of anuria. Not only was the severe pain in the back relieved in every case, but a subsequent flood of urine took place within one to several hours. The treatment should be of 30 minutes' duration, with maximal bearable intensity short of blistering, and should be repeated hourly until the flood of urine starts. In cases of not purely reflex anuria, which may be due partly to mechanical obstructions and partly to their reflex action, considerable amounts of sediment may appear in the first portions of urine.

Before deciding to use the artificial kidney, this very simple method should be tried. It is essential, however, to use classical and not short-wave diathermy, because of its specific action on the vascular nervous supply, as I have explained in my text-book on clinical diathermy which I hope will be published in the near future.—I am, etc.,

Manchester. K. F. NAGELSCHMIDT.

Poliomyelitis Vaccination

SIR,—The difficulty of immunizing against poliomyelitis as your correspondent, Mr. M. H. F. Johnson, suggests (October 1, p. 757) is that, apart from considerations of the safety and efficacy of the vaccine, the majority of strains of virus can only be propagated in monkeys, supplies of which are totally inadequate for any large-scale production of vaccine. If he wishes to know more on the question he might read the article by W. McD. Hammon on immunity in poliomyelitis in *Bacteriological Reviews* (September, 1949, **13**, 135).—I am, etc.,

Birmingham. B. R. SANDIFORD.

Aetiology of Erythema Nodosum

SIR,—Dr. S. A. Doxiadis, in his article on the aetiology of erythema nodosum (October 15, p. 844), stressed the importance of erythema nodosum as a signal of primary tuberculosis infection in children. My experience, based on 2,124 cases of childhood tuberculosis seen in the Dublin Corporation's primary tuberculosis clinic, may be of interest. This clinic was established in 1945, and the material is obtained from tuberculosis clinics, children's hospitals, and general practitioners. I have found only 61 cases of erythema nodosum in the total of 2,124 children—i.e., 2.8%. These 61 cases were all tuberculin-positive.

I would be interested to know if the incidence of erythema nodosum is greater in Dr. Doxiadis's material than has occurred in our case material in Dublin. Could Dr. Doxiadis give any estimate of the number of primary infections which had to be reviewed to produce the 100 cases of erythema nodosum published in his instructive article?

Compared with Scandinavian figures, our incidence of erythema nodosum is remarkably low. Every case was carefully questioned on this point in case the parents considered this manifestation of primary tuberculosis too trivial or did not connect it with the child's illness. My view, based on experience in an Irish sanatorium, is that erythema nodosum, as a sign of primary tuberculosis, occurs in the older age groups. Probationer nurses often show their primary infection by this sign. In Norway the age distribution curve for erythema nodosum presents a sharp maximum in the 20–25 age group. In Scandinavian countries primary infection occurs mostly in young adults, and childhood infection is rare. In Ireland childhood infection is common. As erythema nodosum is principally an affection of adolescence, this may account for the high incidence of this sign in Scandinavia (30%) and its low incidence in childhood primary tuberculosis here (2.8%). Eight of this group of 61 were under 5 years of age—all the others were in the 5–14 age group. Following the usual trend of this allergic reaction, 39 cases occurred in girls and 22 in boys.

The time interval between this outward sign and radiological evidence of primary infection was studied. I have observed that the erythema nodosum often preceded the *x*-ray evidence by one to three months; but in two cases pleural effusion showed, one six months later and one a year afterwards. I think it is of great importance that these cases should have repeat *x*-ray films, since films, including laterals, taken only on one occasion may miss the lesion. Some of our cases had *x*-ray evidence when the erythema was noticed, but two other cases which were tuberculin-positive showed no radiological evidence, although each had three *x*-ray examinations at intervals. Another interesting case had two attacks of erythema nodosum, the primary infection being diagnosed at the second manifestation. This last case, in a child aged 10 years, had a history of erythema nodosum diagnosed at a city hospital in April, 1944. She had a second attack when seen at the primary clinic in March, 1945. Her sputum was then positive; B.S.R. was 17 mm. in one hour, and there was cavitation seen on *x*-ray examination. She died in a sanatorium in February, 1948. This was the only death in the erythema nodosum group.

Perhaps Dr. Doxiadis can confirm my observations that erythema nodosum often precedes the radiological evidence of primary tuberculosis infection in children.—I am, etc.,

Dublin. M. DUNLEVY.

The Acute Throat

SIR,—In Dr. T. Anderson's very thorough article on the acute throat (October 15, p. 860) he states, referring to penicillin: "Local therapy by lozenges and so forth is therefore completely inadequate and systemic administration in high dosage is indicated." He then goes on to state that injections of the soluble compound four-hourly, or the insoluble procaine penicillin two or three times a day and later less frequently, are indicated for seven days. Later, referring to sulphonamides, he remarks, "The efficacy of these drugs has never been convincingly demonstrated in such conditions."

I feel I must disagree. One sees all varieties from mild to severe cases of tonsillitis (mostly caused by the haemolytic streptococcus): the mild cases nearly all clear up with penicillin lozenges and possibly an aspirin mixture, and the severe nearly all clear up with lozenges aided by sulphonamides by mouth and nearly, if not all, in two to five days. Very few G.P.s have the time to give all the recommended injections; the district nurses cannot possibly afford the time; the hospitals are too full; and most patients to-day cannot afford private nurses or nursing-homes.—I am, etc.,

Hove, Sussex. W. A. PORTER.

Sex Hormone Upset in Africans

SIR,—Dr. J. N. P. Davies's paper (September 24, p. 676) on this subject offers a hypothesis which would, if confirmed, throw a good deal of light on some of the perplexities of Bantu medicine. Being at present engaged on a clinical study of malnutrition in Zulu children, we would wish to comment on one or two points raised by Dr. Davies, especially where our own experience differs from his findings further north.

Trowell's findings regarding the prevalence and nature of the syndrome of kwashiorkor (malignant malnutrition) are amply in accordance with the situation in Zululand, but the suggestion made in the paper that few African children escape without at least a mild attack owing to the prolonged period of breast-feeding and the absence of a proper weaning period appears contrary to our findings. Traditionally the breast is supplemented from birth by sour maize porridge (*p*H 4–6), and breast-feeding (other than the mere act of dangling the child on its grandmother's shrunken breast) is usually discontinued by the end of a year, the child then being fed entirely on maize porridge with a little sour milk if available. Weaning may therefore be said to be going on all the time and to be extremely gradual.

Further, we have been able to induce a considerable number of mothers to feed wholly on the breast for six months and then to wean over the next three or four months, using maize products and milk. It would not appear so much that prolonged breast-feeding and the absence of a proper weaning period were at fault as what a child is fed on during and after weaning. Malignant malnutrition is common in children who have been weaned slowly and breast-fed for a "normal" length of time. Preliminary studies have shown that children wholly breast-fed to six months teeth two to three months earlier than their fellows who are fed on the traditional breast-and-porridge

routine. We hope to publish detailed studies at a later date on this matter.

Infertility does not seem so great a problem in Zululand as Dr. Davies describes in Uganda. Of 243 women (a small figure and part of an uncompleted series) past childbearing age, eleven (4.5%) had had no children, while 74% had four or more children.

While umbilical hernia is extremely common in Zulus (a great many of these hernias appear to undergo spontaneous regression about puberty), inguinal hernia appears relatively rare. In 5,000 admissions we recorded only six cases, but it must be remembered that a majority of males are away from this area for many months each year, working in the mines and industry.—We are, etc.,

E. A. BARKER.
MARGARET BARKER.

Significance of Convulsions in Infancy

SIR,—The correspondence on convulsions in infancy (September 3, p. 547, and September 10, p. 598) raises the question whether hyperpyretic convulsions are necessarily the forerunners of epilepsy in later life. This is still a controversial issue.

On the one hand, Peterman[1] maintains pessimistically that every convulsion in a child, unless it is caused by encephalitis, meningitis, or poisoning, has to be considered as the first manifestation of a later epilepsy. In his series of 55 cases of convulsions associated with fever an electroencephalogram was done in 34; only five had normal tracings, and in 35 the diagnosis of epilepsy had to be given subsequently. On the other hand, Neyroud[2] is more optimistic: he states that in the majority the hyperpyretic convulsions may be considered as a common accident which has nothing to do with epilepsy and the prognosis of which is favourable. In his series of 70 children the electroencephalogram was normal in 57, doubtful in nine, definitely abnormal in four, and two showed epileptic patterns.

These extremes will have to be reconciled by further research. Apparently some children will have convulsions when a certain set of circumstances is favourable for their initiation—e.g., fever, with its hyperventilation, and changes in the water metabolism. These conditions may never be imitated later on in life and no epilepsy will ensue.

The therapeutic question, in my opinion, boils down to this: there is no need to start anticonvulsant treatment in every disclosed dysrhythmia so long as it does not give rise to symptoms such as manifest epilepsy, behaviour disorders, or irritability. In febrile convulsions, when no electroencephalogram is available for the elucidation of the case—and at present it is not for a good many general practitioners—the exhibition of antipyretics and phenobarbitone whenever a febrile illness makes its appearance will be all that is necessary. This seems to me a better scheme than that suggested by Dr. G. Daynes (p. 547), who advises anticonvulsant drugs "during the years when the threshold is low." There is no knowing when to discontinue and also a risk in a case of idiopathic epilepsy of status epilepticus after withdrawal of prolonged anticonvulsant treatment.—I am, etc.,

E. GUTHANER.

Treatment of Basal-cell Carcinoma

SIR,—As a dermatologist who over a period of years has treated a very large number of rodent ulcers with radiation, I would like to draw attention to one point in connexion with their aetiology which I feel should have some bearing on the selection of treatment. Among the cases I have treated there has been a number of "recurrences" in excision scars. Knowing who operated in most of these cases, I have not often entertained any suspicion that the lesions were not widely enough excised in the first place.

I think that most of us to-day recognize trauma as the cause of a considerable proportion of the cases of basal-cell carcinoma seen. Patients present themselves with a history of having had a scratch from a pin, a rose thorn, etc., or a cut with a razor blade, which healed but broke down to form a "sore" which would not clear up. In other cases the original injury never healed. In a person with a proclivity to develop rodent ulcers a surgical incision constitutes a greater skin injury than does a scratch with, say, a pin or a rose thorn. I believe that many of the so-called "recurrences" are not really recurrences at all. In my opinion a basal-cell carcinoma had developed in an excision scar in a person with a tendency to develop skin malignancies. Quite recently I saw two cases which illustrate this point.

The first was in an elderly woman who three years ago had a small microscopically proved squamous-celled carcinoma excised from the side of her neck because she could not spend enough time in the city to undergo a course of radiotherapy. She returned recently with two basal-cell carcinomata, one towards either side of the 3-in. (7.5-cm.) excision scar. She had keratoses and another rodent ulcer as well. The second case was that of a woman who had had a mastectomy done some years ago and who presented herself with two basal-cell carcinoma (proved by biopsy) in the mastectomy scar. She was a freckler and had keratoses on the hands and face as well.

I am bringing this point up because I feel that patients who show evidence of a tendency to develop malignant conditions of the skin, keratoses, pigmented patches, etc., are much more likely to develop new basal-cell carcinoma in excision scars than patients who show none of these stigmata. I feel it is much safer to treat them with radiation than by excision.—I am, etc.,

Identification of Microfilaria

SIR,—I have for a long time been interested in getting a quick method, of value in field work, by which the various species of microfilaria could be identified. Lately I have used the brilliant-cresyl-blue method as a vital staining, and I have been surprised at the rapidity and efficiency of the method, which is as follows.

Slides are prepared by dropping on them a drop of a saturated alcoholic solution of brilliant cresyl blue. On the dried slides a drop of blood is placed. A cover slip is placed over the drop, the edges sealed off with vaseline, and the slide examined immediately. The microfilariae will be found to survive for about five minutes, and the granules will be distinctly stained, allowing easy identification.

Medical Services of the Armed Forces

SIR,—The scope of Major E. A. Smyth's article (October 1, p. 751) is so large that detailed comment on all its points is difficult. May I write on one or two he has not mentioned?

(1) Could not the smaller formations, such as field ambulances, have a non-medical adjutant for administration purposes? While fully admitting the necessity for medical officers in these units to be well versed in man management—which is inborn, not acquired—training, discipline, strategy, map-reading, etc., it always seemed to me a gross waste for medical men to be chained to a desk for hours every day, grappling with audit boards, imprest accounts, courts of inquiry, summaries of evidence, messing, rations, and pay, when they should have been out with their men, getting to know them, supervising training and exercises.

(2) Has, I wonder, any conference been called at the Staff College to which distinguished Territorial officers (who commanded field ambulances and casualty clearing stations by the dozen, and were A.D.M.S.s to at least four or five famous fighting divisions, D.D.M.S.s to at least two corps and to one Army command) have been invited? Could not their elasticity of mind and their genius for improvisation—the acquiring, for example, of thousands of extra square yards of canvas to supersede the miserable pent-houses on the three-tonners—be an asset? Could not their knowledge and experience be made use of in considering future wars? Perhaps this has been done. If not, it is surely overdue.—I am, etc.,

W. A. BELLAMY.

Aylesbury, Bucks.

Paddington Green Children's Hospital

SIR,—Your readers are probably familiar with the decision of the board of governors of St. Mary's Hospital to convert Paddington Green Children's Hospital to adult use and for the reason which has been given for this action—namely, the excess of children's beds in the St. Mary's group over the number recommended in the Goodenough Report. They may also have read the Ministry of Health circular (R.H.B. (49) 132), which together with your annotation entitled "Changes in Use of Hospitals" (October 15, p. 857) encouraged many to believe that the board might reverse their decision. Unhappily, there is no sign of any change of heart.

I am therefore writing, as chairman of a committee which is composed mainly of members of the local public and which is non-political, to give publicity to this fact. It seems right that the profession should know exactly what is happening, because this is certainly no academic medical dispute. In Paddington and neighbouring boroughs a great wave of spontaneous public indignation has occurred and now finds expression through the Save the Children's Hospital Committee. Twenty thousand people, mostly local, have already signed a petition, and further evidence is found in the resolution passed by the Paddington Borough Council on November 1, after a special committee appointed by them had investigated the matter, deploring the decision of the St. Mary's board. It is apparent that the board of St. Mary's Hospital has failed completely to understand the depth of feeling which their action has aroused. Their explanation, that students must be properly taught, does not carry conviction. Hitherto there has been no suggestion that the doctors produced by St. Mary's are less capable than their colleagues.

My committee feels a need to work hard to bring about the final decision in the near future, since a hospital which is under threat of annihilation works under strain, and it is only a matter of time before signs of deterioration must appear through the unwillingness of serious workers—whether doctors, nurses, or others—to spend their energy on tasks which have no relation to a future.

Surely the proper course is to allow the Children's Hospital to continue the work which it has carried on with acknowledged success for 66 years, and to allow its teaching facilities to be transferred to another teaching hospital group less fortunately situated than St. Mary's.—I am, etc.,

MICHAEL HARMER,
Chairman, Save the Children's Hospital Committee.

London, N.W.1

The G.P. and E.C.T.

SIR,—The experience mentioned by Dr. Donald M. O'Connor under the above heading (October 29, p. 984) has been unfortunate, but it may have been due in some instances to factors other than mere inefficacy of E.C.T. Many of our modern techniques (E.C.T., insulin coma, prolonged narcosis, leucotomy, etc.) do not so much cure the patient as render him more accessible and responsive. In other words they pave the way for other therapeutic methods, and if these are not applied the patient remains half-treated and incompletely recovered.

Some cases, after special physical treatments, require psychotherapeutic help, while many need weeks, even months, of intensive rehabilitation under good hospital conditions. Whether this takes the form of occupational therapy, physical training, and special games for one patient, of outdoor sport, general entertainments and competitive outlets for another, or of cultural activities, social functions, and club conditions for yet another, such rehabilitation is unlikely to be available except to in-patients, and it is in hospital that proper combinations of all the required activities can best be prescribed, organized, and carried out.

It is unfortunate that there has been a temptation to hail the newer physical treatments not only as applicable to too wide a range of conditions but also as complete and sufficient therapies in themselves, forgetting that mental stability and a resumption of normal life cannot always be achieved without the application of rehabilitating and resocializing methods before the patient returns to his home, so that if he leaves hospital without adequate treatment during his convalescence the risks of a relapse will naturally be all the greater.—I am etc.,

Warrington, Lancs. J. ERNEST NICOLE.

Catalogue of Medical Films

SIR,—Two years ago, with the aid of a generous grant from the Royal Society of Medicine, the medical committee of the Scientific Film Association set up a "master file" of data on medical films. It includes details of production, distribution and content, and a provisional grading of each film. It covers all the films in existence in this country up to 1946 and is being added to constantly. Covering over 800 films, it provides the most comprehensive collection of data about its medical films that any country in the world (with the possible exception of Canada) can show. From this master file was prepared the RSM-SFA catalogue of medical films. The first edition of 1,000 copies was exhausted in twelve months, a remarkable index to the widespread interest in medical films.

We are faced with the problem of deciding whether to reprint or to prepare a new edition. As the lay-out of the first edition was cramped by paper shortage, and as there are many new films to be included, we have decided in favour of a new edition. We are constantly getting requests from abroad as well as from this country, and we ask the hospitality of your columns for this explanation of why the catalogue will not be available for some months yet.—I am, etc.,

4, Great Russell Street, London, E.C.1.

KENNETH GOADBY,
Chairman, Medical Committee, Scientific Film Association.

POINTS FROM LETTERS

Retinal Arterial Occlusion in Migraine

Dr. LEO HAHN (Leicester) writes: I have been most interested in Dr. G. S. Graveson's article (October 15, p. 838), which provides an important contribution in support of the time-honoured vascular theory of the migraine attack. As long ago as 1923 I accepted the view that the migraine paroxysm is initiated by a cerebral angiospasm and introduced the potent vasodilator drug papaverine into the treatment of migraine (*Dtsch. Z. Nervenheilk.*, 1923, 77, 191). Forty milligrammes of papaverine hydrochloride, if given intravenously—very slowly in order to prevent a fall in blood pressure—early in the attack, rarely fails to arrest the paroxysm. Administered orally in much higher doses (100 mg. t.d.s.) for long periods, the drug is in most cases effective in reducing the frequency of attacks. The effectiveness of this treatment has been confirmed by several authors. . . . Dr. Graveson's cases illustrate very well that occasionally the cerebral disturbances characteristic of the aura and caused by the initial angiospasm may substitute the attack. Together with Dr. E. Kraupa I have reported a case of spasm of the central retinal artery producing the picture of "acute retinal ischaemia" with subsequent amaurosis in a girl 5 years of age (*Klin. Mbl. Augenheilk.*, 1921, 66, 829). Papaverine treatment restored within a few weeks the retinal circulation and the visual acuity. It seems probable that the early administration of papaverine in cases as reported by Dr. Graveson could prevent the thrombotic vascular occlusion.

Migraine and Calcium Deficiency

Dr. N. M. STEPHEN (Saxmundham, Suffolk) writes: With reference to the article (October 15, p. 838) by Dr. G. S. Graveson calling attention to a condition of arterial spasm in migraine, I have the following observations to make. Acting on the assumption that migraine might be considered to be a vasomotor disorder involving changes in the vascular tone of the arteries of the meninges, I made an attempt in a series of severe cases of migraine to try the effects of calcium therapy. The form of calcium used was colloidal calcium with vitamin D. The results were surprisingly successful. Therefore I have concluded that migraine is due in part at least to a genuine calcium deficiency. The treatment was used empirically, and I had no facilities for carrying out estimations of the serum calcium in the patients treated. An interesting fact is that one of the patients stated that she had been free from attacks of migraine while she was pregnant. This might be explained by supposing that all supplies of calcium are mobilized during that period and are therefore more readily available. All the patients referred to had already experienced all the usual forms of treatment—i.e., aspirin, phenobarbitone, and ergotamine tablets. The time interval between the injections tends invariably to increase, and a space of two to three months may elapse before the next injection becomes necessary.

Obituary

Sir HERBERT EASON, C.B., C.M.G., M.D., M.S. F.R.C.S.

Sir Herbert Eason, president of the General Medical Council since 1939, died at Guy's Hospital on November 2 at the age of 75. He had attained distinction in the practice of a medical specialty, in hospital administration, in the government of a university, and as president of the body controlling the training and discipline of the medical profession. So closely associated was he with academic and public life that it was often forgotten that he was also an ophthalmic surgeon who had contributed much to the literature and teaching of ophthalmology. At Guy's Hospital he was chief of the ophthalmological department for more than thirty years. Herbert Lightfoot Eason was born in London on July 15, 1874, and received his education at University College. From there he went to Guy's medical school, qualifying in 1898, and taking his M.D. degree in 1901 and his M.S. a year later. In 1902 he became resident warden at Guy's, and in the following year dean of the medical school, a post he held until 1912. During the first European war he served with the rank of lieutenant-colonel as consulting ophthalmic surgeon to the Forces in the Mediterranean, Egypt, and Palestine. He was mentioned in dispatches, and awarded the C.M.G. in 1917 and the C.B. in 1918. His experiences in the Near East are recorded in *Guy's Hospital Reports* of that period and in the *Transactions* of the Ophthalmological Society, of which at that time he was an active member.

[Russell and Sons

Herbert Eason's appointment as superintendent of Guy's Hospital took place in 1920, when Sir Cooper Perry retired, and he made his home in the elegant old building, since destroyed by enemy action, on the east side of the famous court in which stands the statue of Thomas Guy. This post he held for not far short of twenty years, during which time many notable developments took place in the hospital. One of these was the opening by the Prince of Wales, afterwards Edward VIII, of Nuffield House for private patients, situated in the hospital grounds.

The affairs of the University of London, then in a transitional stage, began to claim his attention in 1911, when he was elected to the Senate as a representative of the Faculty of Medicine. He also represented the Senate itself on the University Court. Eason was chairman for various periods of the library and finance committees and of the advisory council, and in 1935 he became vice-chancellor. This office he held until 1937, when the Senate appointed him to the post of Principal of the University for a period of four years. The construction of the great university buildings in Bloomsbury, which during the war were the home of the Ministry of Information, had already been started, and Eason's appointment to the post of principal synchronized with the flying of the university flag from the completed tower. These four years were important ones in the history of the university. Eason had already been a member of the departmental committee of the Board of Education on the reconstitution of the university, and to a large extent under his guidance the reconstitution was effected and great progress made in all branches of its work. Research was promoted by scholarships and other means, and a large university professoriate was built up. At the end of his term of office as principal London University had 250 professors, 167 readers, and nearly a thousand recognized teachers.

Eason's outstanding work for the university by no means exhausted his activities in the educational field. He was for six years a member of the departmental committee of the Ministry of Health on postgraduate medical education, and he served as a member of the governing body of the British Postgraduate Medical School, which, like the twelve undergraduate schools in London, is a school of the university. It was his association with the University of London which brought him on to the General Medical Council; he took his seat as its representative in 1925. His already great administrative experience proved most useful in this field. He took a prominent part in the Council's discussions on education; he also became co-treasurer of the Council and a trustee of the English Branch. In whatever activity he engaged he seemed to make an effortless progress towards the top, and when Sir Norman Walker retired in 1939 Eason was the unanimous choice of his colleagues as President. He brought to the chair a long business experience as well as a natural authority, wisdom, and urbanity. A fierce light often beats on the G.M.C., but Eason was neither flattered nor intimidated. Throughout his career he had the most jealous regard for the ethics of his profession. He carried this to such a point that in his various official positions he would not allow his name to appear in the newspapers if it could be avoided. When newspaper men called on him for information he would tell them that they might say that the superintendent of Guy's took such and such a view or that the principal of the University of London had this or that intention, but the name of Eason they must not print, and generally his wishes were respected.

In a lecture he once delivered to students at Guy's Hospital he said that the simple rule which should govern them in their professional career was that same unwritten rule which guided the true Englishman in all circumstances—namely, that certain things are not done. This rule, he said, extended from trivial affairs of taste right down to cheating or embezzlement. "Gentlemen," said Eason, "the code of conduct summed up in the words 'it is not done' begins in the public school and goes on through the university, and remains with a man throughout his career. Keep those words in mind, and you will never come before the tribunal over which at the moment I have the honour to preside."

Eason was a member of the General Nursing Council, on which he represented the Ministry of Health. He was a co-opted member of the Public Health Committee of the London County Council, a member of the General Council and of the Economy Committee of the King Edward's Hospital Fund for London, a J.P. of the County of London, and a trustee of the Beit memorial fellowships for medical research. He was an honorary Bencher of the Inner Temple, and he contributed the articles on ophthalmology to French's

Index of Differential Diagnosis. Like some others who have occupied leading positions on the General Medical Council, in order to remain unembarrassed in dealing with disciplinary cases he stood outside the membership of the B.M.A., but he was sympathetic to the Association's aims, and in earlier years he rendered it good service as a member of the Ophthalmic Committee which helped to sponsor the National Eye Service. His name appeared as a knight in the birthday honours list of 1943.

RICHARD LAKE, F.R.C.S.

Mr. Richard Lake, who was for many years a well-known ear, nose, and throat surgeon practising in London, died in a nursing-home at Bristol on November 1 at the age of 87.

Richard Lake was born at Sittingbourne, Kent, on December 14, 1861, and was a student at St. Thomas's Hospital, where he qualified in 1885. In the same year he took part in the Sudan campaign as a surgeon of the National Aid Society. This was before the organization of the Red Cross, and he undertook similar work in the Servo-Bulgarian war, for which he was decorated by both the Servian and Bulgarian Governments. Returning to England, he took the F.R.C.S. in 1890, and from then onwards specialized in the treatment of diseases of the ear, nose, and throat.

Mr. Lake was appointed surgeon laryngologist to Mount Vernon Hospital in 1897, and in the following year began his long association with the Royal Ear Hospital. For many years he was consulting surgeon in his specialty to University College Hospital and to the Seamen's Hospital, Greenwich, and he was president of the otological section of the Royal Society of Medicine. During the 1914–18 war he served as aural surgeon to the R.F.C. Hospital and to Princess Christian's and Robert Lindsay's Hospitals for Officers. For four years from 1924 he was Geoffrey E. Duveen Lecturer on otology in the University of London. He was also at one time president of the West London Medico-Chirurgical Society. He published a number of papers on tuberculosis of the larynx, simulated deafness, aural vertigo, re-education of the deaf, mastoid suppuration, and other subjects in his specialty.

C. O. HAWTHORNE, M.D., F.R.C.P.

J. M. A. writes: May I pay tribute to the memory of my patient and friend, Dr. C. O. Hawthorne (October 29, p. 986)? His great age brought increasing infirmity, but he never once complained. The disability which interfered with the use of his typewriter was a blow to him, and his friends missed his pungently witty notes. His command of the English language, verbal and written, was superb, and no man was more widely read. He was equally at home in the German language. When in 1942 his house in Hove was almost destroyed by a bomb he maintained an admirable philosophic calm. His interest in his profession and in the British Medical Association remained unabated to the end of his life. To the last his amazing memory was unimpaired, and there was no senile reiteration of old stories, but a gentle irony when discussing current events and modern medical politics. Only this year he published a popular science pamphlet, *The Human Body: A Justification.* Physically and mentally he was a big man, and beneath his reserved manner lay a vast understanding of human frailties. Although he outlived most of his contemporaries, he will be missed by all who knew him.

Dr. Bernard Myers writes: As a colleague of Dr. C. O. Hawthorne for many years at the Royal Waterloo Hospital I would like to mention the high respect in which Hawthorne was held by his colleagues for his downright honesty in his views, even if disagreeing with those expressed by the other members of the medical committee. He always spoke sound common sense and was fair in argument. If his external manner was apt to be severe, that was not the real man, for when we lunched together his genial and kindly spirit was evident. Those who knew him well will mourn the passing of a sound physician, loyal colleague, and good friend.

Dr. Eva McCall writes: May another old student of Dr. C. O. Hawthorne also pay a tribute to his memory? Dr. Hawthorne lectured to the women students in the medical faculty at Queen Margaret College, University of Glasgow, in the 'nineties, and I was privileged to be one of those. He was a most inspiring teacher, and dressed the dry branches of materia medica with glowing tints, so much so that this dull subject became quite fascinating, and I owed him a lifelong debt of gratitude for his magnificent teaching. It was an incalculable loss to the university, where he would have filled a professorial chair with great distinction.

Dr. ARTHUR HILL BURNETT died suddenly on October 7 at the age of 68. He was born in Southampton and educated at King Edward VI School and the old Hartley College. He carried out his medical training at Edinburgh University and the London Hospital, qualifying in 1904. He held house appointments at the British Lying-in Hospital, Endell Street, at St. Mary's Hospital for Women and Children, Plaistow, and at the Kensington Infirmary, London. For a time he was a ship surgeon and visited many parts of the world. During the first world war he served in the R.A.M.C. with the rank of captain. In 1919 Dr. Burnett was appointed honorary anaesthetist to the Royal South Hants and Southampton Hospital, and medical officer to St. Mary's Institute. When the latter building was blitzed in 1940 he continued his work at Moorgreen Hospital. Apart from conducting a busy practice and his institutional work, he gave a large part of his time to the administration of anaesthetics at the Royal South Hants Hospital, where he was recognized as an expert anaesthetist. Retiring from this post during the recent war, he was appointed honorary consultant anaesthetist to the hospital. Dr. Burnett was an able physician, a skilled anaesthetist, and the pleasantest of colleagues. His contemporaries will long remember his happy disposition, his sincerity, and his great friendliness. To his widow and sons many colleagues and friends will extend their deep sympathy. —S. N. L.

Dr. CHARLES ROPER, of Rochester, who died there on October 17, was the younger son of the late Charles Roper, of South Kensington. He was born in 1877, and was educated at St. Paul's School, where he obtained a Tancred studentship in physic to Caius College, Cambridge, going into residence there in 1895. After taking the Natural Sciences Tripos he was awarded a scholarship to the medical school of the Westminster Hospital, and graduated B.C. in 1903 and M.B. in 1904. He proceeded M.D. in 1911, and took the Oxford D.P.H. in the same year. After filling house appointments at the Westminster Hospital he held for a few years an appointment as medical officer in Assam. Later, after his career had been interrupted by tuberculosis, he took up the study of that disease as a specialty. He was medical superintendent of Tehidy Sanatorium in Cornwall, and then tuberculosis officer for Kent, with headquarters at Rochester, and there he remained for the rest of his professional life. He had contributed on several occasions to the literature of his specialty. Dr. Roper was chairman of the Rochester, Chatham, and Gillingham Division of the British Medical Association from 1930 to 1932. He married Ethel, daughter of Mr. G. A. Dick, who survives him.

ANDROGENS
in Gynaecology

The rationale for the use of androgens in the female is based on their ability to produce a reflex pituitary inhibition. Androgens may therefore be substituted in certain conditions where œstrogens are contra-indicated or have been tried and found ineffective. The clinical application of androgens in the female includes hypermenorrhœa, whether functional or of menopausal origin, mastodynia, pre-menstrual tension, dysmenorrhœa, frigidity and more recently, the treatment of advanced carcinoma of the breast.

The British Schering range of androgenic preparations includes:

'TESTOVIRON' for parenteral administration; it is an oily solution of testosterone propionate.

'ORAVIRON' for oral and sublingual therapy, which in adequate dosage reproduces all the known effects of parenterally administered androgen.

'TESTOVIRON' Ointment is available for topical application when a local effect only is required.

DANGEROUS DRUGS IN LOCKED CAR

A doctor was recently fined for keeping dangerous drugs other than in a locked receptacle.[1] His appeal, by way of case stated by Lord Ilkeston, the stipendiary magistrate for Birmingham, was heard in the King's Bench Division on October 19. Information against the doctor was originally preferred by a chief inspector of police, who alleged that on January 9, 1949, the doctor had contravened regulation 5 (2) of the Dangerous Drugs Regulations, 1937, which provided that "every drug . . . in the actual custody of a person authorized by this regulation shall, except when the necessities of the practice of the profession . . . by virtue of which that person is authorized . . . require, be kept in a locked receptacle which can be opened only by him or by some other person authorized by virtue of this regulation."

The facts proved before the magistrate were as follows: The doctor, as a registered medical practitioner, was a person legally authorized to be in possession of drugs to which the Dangerous Drugs Act, 1920, and the regulations made under it applied. On January 9 the doctor went to the cinema in his car, which he left in a car park with the doors locked. Inside the car was an unlocked leather case containing a number of dangerous drugs. On leaving the cinema he found that the car had been stolen. It was recovered on January 12, unattended and with all the doors wide open and the unlocked leather case containing the drugs on the rear seat. The drugs were handed to a police inspector, who later saw the doctor. The doctor admitted that the drugs were his.

It had been contended for the prosecution that a locked car was not "a locked receptacle" within the meaning of regulation 5 (2), and that if the doctor wished to take advantage of the exception in the sub-regulation the burden of proving the necessary facts for that purpose was on him. For the defence it was held that the doctor had complied with the regulation by leaving the drugs in an unlocked case in a car all the doors of which were locked. The key to the car was in the doctor's possession and was peculiar to that car. The word "receptacle" was not limited to the container of the drugs; the real test was whether the drugs were safely under lock and key. It was also argued that it was essential for the doctor to have these drugs easily accessible in case of emergency, and that it was much safer for him to leave the drugs in an unlocked case in a locked car than to leave them in a locked case in an unlocked car. The magistrate found the charge proved, and the doctor was therefore fined.

Judgment

The Lord Chief Justice, giving judgment,[2] said that in his opinion the regulation contemplated that drugs of this kind should be permanently and regularly kept in some locked receptacle. It was impossible to say that a motor-car was a "receptacle" within the meaning of the regulation. If it were, it could be held that if a doctor left dangerous drugs in his house and then went out and locked all the doors the drugs had similarly been left in a locked receptacle within the meaning of the regulation. A motor-car might be described as a receptacle for luggage, but the regulation must be construed so as to effect the obvious purpose of the Legislature. A motor-car which had constantly to be locked or unlocked, according as it was being driven or parked, could not fairly be brought within the terms of the regulation as being a "receptacle." The appeal was therefore dismissed.

1 *British Medical Journal*, October 8, 1949, p. 819.
2 *The Times*, October 20, 1949.

According to a report issued by the International Tuberculosis Campaign about 16,000,000 children and young adults in the countries in which Unicef is conducting feeding programmes had been tuberculin-tested and about 7,500,000 had been vaccinated with B.C.G. up to August 1, 1949.

Medical Notes in Parliament

NATIONAL HEALTH SERVICE (AMENDMENT) BILL

Lord SHEPHERD in the House of Lords on November 1 moved the Second Reading of the National Health Service (Amendment) Bill, which had already passed the House of Commons (*Journal*, October 29, p. 989). He described the Bill as small and non-contentious. In certain particulars it applied also to Scotland. Its objects were, first, to elucidate and amend those provisions in the National Health Service Acts which prohibited the sale of practices of doctors in the Service, and which compensated them for the loss of goodwill, in regard to partnerships of a mixed character. Secondly, the Bill implemented promises of amendment made to the medical and dental professions. Thirdly, it made certain minor administrative amendments, and, fourthly, it removed doubts regarding some of the provisions of the original Acts.

Great difficulty had been experienced in framing clauses dealing with partnerships and with the sale and purchase of medical practices, and even when these Bills became Statutes a good deal of discontent had remained concerning their effect. Mr. Bevan had appointed a committee under Mr. Justice Slade to examine those parts of the Acts which referred to partnerships, and he had completely accepted the report of this committee. The recommendations made in that report were provided for in the Bill. The Government wanted to encourage the formation of partnerships in the medical profession, believing this to be of advantage to doctors and to their patients. There would be as little interference with partnerships as possible. Lord Shepherd understood that there were only 50 "mixed partnerships" affected by the Bill, and the number of doctors concerned was only 150.

Part II of the Bill was simpler but of great interest. For some time the medical ranks had been agitated by a fear that under the Acts a full-time service might be established. Indeed, it was possible under the original Acts for Orders to be introduced into both Houses for the purpose of placing the medical service upon a full-time basis. Such a power had existed since the National Health Act of 1912. Mr. Bevan, however, had given a pledge in the House of Commons on April 7 that it would be made impossible by regulation to place the medical profession effectively on a full-time basis. Mr. Bevan had also said that the Government had no intention of establishing a full-time practice and that he would make this clear in an amending Bill.

Minor Amendments

Among other things the Bill referred to the tribunal which had power to take out of the Health Service those who must be disqualified. It was made up of a legal chairman, an executive council member, and a member of the profession concerned. The last member would be appointed by the Minister of Health, and at the suggestion of the medical profession would be taken from a panel representing the various interests of the profession concerned. The Minister had agreed to this.

Another point related to the costs of the establishment of local committees of doctors, chemists, and opticians. The professions concerned had suggested that the expenses of these committees should be borne out of block deductions from the fees to be paid to them. This had the advantage of maintaining the independence of the professions. The time in which doctors could make a claim for midwifery fees was extended to three months. Dentists would have the same rights as doctors in taking into hospitals as paying patients those of their clients who did not wish to be Service patients. The Minister held that as 95% of the population were in the scheme the number of persons among whom private practices could be built up was so small that they could receive the advantages of the hospital service without getting unduly in the way of those who were in the scheme.

In a great service relating to the hospitals questions of labour or remuneration were bound to arise. It was proposed, in

Clause 13, that the Conciliation Act of 1896 and the Industrial Courts Act of 1919 should be applied. A special tribunal of the Industrial Court would be appointed to deal with disputes arising out of remuneration or other conditions of service.

It was also intended to provide that men who were in the hospital service but desired to sever their connexion with it for a period should be enabled to do so but still remain in the superannuation scheme. It was desirable that medical officers should be able to take short-service contracts in the Colonial Medical Service while continuing to contribute to the Health Service superannuation scheme. Lord Shepherd went on to speak about clauses introduced at the request of outside organizations. District nursing associations and other bodies found much of their former work undertaken by hospitals and other authorities. The Bill would permit these bodies to hand over to the Health Services any property for which they no longer had any use but which existing trust deeds might have prevented them handing over. Clause 24, which applied to Scotland only, enabled children under 16 in that country to be treated on the initiative of parents or guardians as voluntary patients in mental hospitals. This would bring Scottish law into line with English law. Another provision, primarily a mental health matter, enabled a charge for board and lodging to be made to hospital patients who went out to work in the later stages of their recovery.

Lord Shepherd confessed that the Bill was somewhat disjointed. It was a list of small things promised, of little difficulties to be remedied, and of frictions to be eased. It was the first, but it would not be the last, National Health Service (Amendment) Bill. It was a matter for congratulation that the Government, having found that some adjustment was required, had taken early steps to bring it about. In the course of time as the Service grew the Government might have to call on Parliament to make other adjustments, but he believed that no attempt would be made to undermine the main principles on which the Acts were based. He moved that the Bill be read a second time.

One Shilling on Prescriptions

Lord LLEWELLIN said that had the promises which this Bill was to fulfil not been made the National Health Service might never have started. Although it was a minor Bill it did a major piece of work. Three years ago when the National Health Service Bill was discussed in the House of Lords statements were made that the partnership clauses would not work. Last time Lord Horder, Lord Moran, and Lord Webb-Johnson were all present in full cry. To-day those three noble Lords were conspicuous by their absence. From that it was clear that the medical profession agreed with the Bill.

He asked Lord Shepherd to tell the House whether the Government intended to use this Bill to effect the payment of one shilling per prescription which had been announced as part of the economy campaign, or whether that proposal would be contained in another measure. He had noted that old-age pensioners were to be exempt from the new charge, and he asked the Government to consider also the inclusion in this exemption of the disabled ex-Serviceman who needed medical supplies for his actual disablement.

Lord CLYDESMUIR said the parent Act had been applied to Scotland with little modification, and Scotland had the Health Scheme with all its mistakes, some of which were becoming evident. The medical services in Scotland were working under strain, and the House would assist those services by approving the Bill. The second part of the Bill provided that regulations should not require specialists to be employed whole-time. There was anxiety among specialists in Scotland about whether this clause was wholly watertight. A case had been instanced of a Scottish hospital in which as a result of administrative action, by advertisement, the door had been closed to anything but full-time employment of specialists.

Lord SALTOUN suggested that the provision for treatment in mental hospitals for children under 16, on the initiative of parents or guardians, might be an interference in Scotland with the boy's Common Law right. In Scotland a boy of 14 was considered capable of carrying on his affairs in all respects except ownership of a heritage.

The Earl of CORK and ORRERY, speaking of the proposed p ment of a shilling on prescriptions, said that two men wh he had consulted had both asked why it was not arranged a patient to pay the tax on his first visit to a doctor. That wo limit the number of people going to see the doctor in first place. It would cut down the mob in the waiting-roo and would obviate the need for the doctor to go on prescrib coloured water. It would reduce the number of old wom sitting there talking when all they needed was a Beecham's p

Lord KERSHAW replied briefly. He was unable to tell Lo Llewellin whether the shilling charge would be brou into the Bill. The matter was under consideration and w regarded as one which should be dealt with promptly. T suggestion with regard to disabled ex-Servicemen would be co sidered sympathetically by Mr. Bevan.

The Bill was then read a second time and was committed a Committee of the whole House.

NURSES BILL

The Nurses Bill, which had its second reading in the Hous of Commons on October 21 (*Journal*, November 5, p. 1056) was considered on October 28 in committee.

Mr. LINSTEAD moved on Clause 1 the first of a series of amendments intended to give an assistant nurse the statutory title of "enrolled nurse" and to describe the relevant committee as the Enrolled Nurses Committee. He said that at the moment there was an anomaly because although these nurses were on a roll called the Roll of Assistant Nurses they had the right to call themselves nurses without using the word "assistant." Whether the House wished it or not many hospitals, particularly the hospitals for the chronic sick, would be staffed by assistant nurses. Anything which would help to bring these girls under the control of the General Nursing Council as assistant or enrolled nurses should be done.

Mr. BLENKINSOP sympathized with the object of the amendment. He said the Government did not regard the term "assistant nurse" as being a final choice. The Ministry had recently shortened the period of training for assistant nurses, and the time was a bad one to choose for suggesting a new name. It would be difficult for the average person to differentiate between enrolled nurses and registered nurses.

The amendment was then withdrawn.

Before the deputy chairman, Mr. BOWLES, called an amend ment on Clause 2 in the name of Mr. WALTER ELLIOT to leav out "Standing Nurse Training Committee" and insert "Nurs Training Authority" he asked for an assurance that there was no more in it than a mere change of name. Otherwise he would have to rule the amendment out of order as conflicting with the money resolution already carried which authorized expenditure by standing nurse-training committees.

Mr. LINSTEAD moved the amendment and said that under the title first proposed the committees might be regarded as subordinate bodies of the regional board. That was not so, and the alternative name "authority" had commended itself to the Royal College of Nursing. Mr. BLENKINSOP was unable to accept this amendment, which was withdrawn.

An amendment by Mr. DIAMOND was also withdrawn, and Clause 3 was ordered to stand part of the Bill after Mr. Blenkinsop had said the Ministry was satisfied that under the Bill as it stood the General Nursing Council was entirely responsible for examinations and could standardize them throughout the country or authorize regional committees to carry them out on whatever conditions the Council considered necessary.

Training and Employment

Sir HUGH LUCAS-TOOTH moved to leave out subsection (2) of Clause 4. He said the purpose of the clause was to separate responsibility for the training of nurses from the employment of nurses. On second reading the House had not discussed how that purpose was to be carried out. He asked the Government to say how this scheme would work. Could a hospital do any training of nurses if it had not previously been approved by the nurse-training committee? If it could not, they might find that the scheme was what Mr. Bevan would describe as

muscle-bound. He also asked whether disbursements in respect of training would be made by the hospitals themselves or whether the nurse-training committee would be able to carry out a scheme within the walls of a hospital. He held it to be important that the actual training should be carried out completely by the hospital. Where there were two different bodies responsible for policy and payment there was danger of conflict. A hospital might require 50 nurses in training for the purposes of employment, but the nurse-training committee might decide that only 30 nurses should be in training in that hospital. How would that sort of question be resolved?

Mr. BLENKINSOP said the intention was first to issue a general indication of the category of expenditure which Mr. Bevan would regard as coming within the nurse-training fund. It would be possible to separate this from the general administrative expenses of the hospital, but some expenses which could be regarded as connected with nurse training could not reasonably be separated from general administrative expenses. To set out the categories of expenditure which the Minister regarded as being separately chargeable would be the first step. Categories of expenditure which Mr. Bevan would regard as coming within this section of the Bill would include the payment of sister tutors, expenditure on lecturers and others, and might also include certain types of building, such as provision for classrooms. Hospital management committees and boards of governors in framing budgets for nurse training would have regard to these specified types of expenditure, which would be open to variation from time to time. On the allocation of expenditure the Ministry hoped to get agreement in the regional committee. In the case of a new teaching centre which could also be used for other purposes of general hospital administration a regional committee might feel that the matter should not be included in the training budget. That was the type of question which would go to the Minister for decision.

Sir HUGH LUCAS-TOOTH asked whether the Government contemplated that the Minister should be able to divide up expenditure which was partly for training and partly for administrative expenses of the hospital.

Mr. BEVAN intervened to say it was perfectly clear that this was intended. The Bill was providing what was available already in the National Health Service to ensure that the academic side of medicine was kept separate and that the provision of apparatus on the secular side was the obligation of the Minister of Health.

The amendment was by leave withdrawn, and Clause 4 was added to the Bill.

Sir HUGH LUCAS-TOOTH moved on Clause 8 an amendment to provide that a finance committee should consist of not less than seven nor more than eleven members.

Mr. BLENKINSOP said the House would be undertaking responsibility which it had better leave to the General Nursing Council if it specified any precise numbers for the finance committee. He believed the general view was that it was desirable for the finance committee to be reasonably small. The amendment was withdrawn, and Clause 8 was ordered to stand part of the Bill. Minor amendments were made to Clauses 12, 13, 15, 16, and 19 on the motion of Mr. BLENKINSOP.

On Clause 21 Mr. BLENKINSOP secured the insertion of a provision that "chief male nurse" should mean a male nurse in charge of the male nurses employed in a mental hospital.

General Nursing Council

A new clause was added to the Bill to provide that membership of the Council and its subordinate committees should not involve disqualification from election to Parliament. Discussing the First Schedule, Mr. HOWARD moved to provide that one member of the General Nursing Council should be a member of the University Grants Committee. Mr. BLENKINSOP resisted the amendment and it was withdrawn.

Mr. BURDEN moved to provide that one member should be a nurse whose name was included in the supplementary part of the *Register* containing the names of nurses trained in the nursing of cases of infectious disease. He said the amendment had the support of the National Association of Local Government Officers. Mr. BLENKINSOP, in resisting the amendment, said he was glad to announce that owing to the decline in the need for fever nurses this part of the *Register* was becoming smaller. New admissions had fallen from 740 in 1946 to about 300 this year. The Government preferred to look forward to the early cessation of special training of this kind and would expect to find within the general training of nurses the necessary knowledge of infectious diseases. The amendment was then negatived.

Mr. SKINNARD moved an amendment to raise the representation of ward sisters on the General Nursing Council from one to two. Mr. HASTINGS supported the amendment and said that ward sisters required representation because they were engaged practically all their time, or ought to be, in nurse training. Mr. BLENKINSOP said it was wrong to assume that the representation of each particular viewpoint must be ensured specifically in the Bill. The amendment was negatived.

Mr. HOWARD thereupon moved that two members of the Council should be registered medical practitioners. He said the best results in nursing were obtained only where there was the closest working partnership between the medical man and the nurse. Mr. BLENKINSOP said in the past the Minister had always ensured representation of the medical profession. There was no intention to depart from that practice, but he preferred not to agree to the insertion in the Bill of the words proposed by Mr. Howard.

Dr. H. B. MORGAN said he failed to see why the medical profession should by statute be included on the General Nursing Council unless in the pending reform of the General Medical Council there was to be a reciprocal arrangement by which nurses would be included. He would tell the B.M.A. Council at its next meeting that he failed to see why the medical profession should ask to have representation on the General Nursing Council. The amendment was negatived.

Mr. HASTINGS then moved to provide that one member of the Council appointed by the Minister should be a person having experience in the nursing of cases of tuberculosis. He said nurses who had practical experience in nursing this disease would be of the greatest help to the General Nursing Council and indirectly to the Government in explaining what was wrong and in getting more nurses for this important class of case. Mr. BLENKINSOP said if it was not possible to meet the need in any other way he would be much inclined to accept the amendment. He hoped that increasingly nurses would gain experience in this field as part of their general training. He believed they would get experience of this field through the general representation of nurses, and he asked Mr. Hastings not to press the amendment. Mr. HASTINGS withdrew his amendment.

Further amendments to the First Schedule were moved and withdrawn and the Schedule as amended was agreed to. The Second Schedule (Standing Nursing Training Committees) was agreed to without amendment. Minor amendments were made on the motion of Mr. BLENKINSOP in the Third Schedule (Mental Nurses Committee). The Bill was then reported to the House with amendments.

Food Hygiene

Mr. SKEFFINGTON-LODGE on October 31 raised the question of food-poisoning and food hygiene. He said that between 1938 and 1947 there had been 3,270 outbreaks of food-poisoning in this country. In 1938 there were 156, as against 964 last year. There was reliable authority for the view that food-poisoning generally was at least three times what it had been before the war. Returns of the Registrar-General for the years 1937–46 recorded 246 deaths from this cause. Mr. Skeffington-Lodge calculated that one-half of the population had at least one meal a day away from home. Midday meals were served in schools to about two-thirds of the school population of the country. Since the war there had been two very hot summers, and many weaknesses on the food front had been exposed. The precautions taken in a cool summer would have to be looked at and revised, for experience showed that they were not adequate to deal with changed conditions and what might be a changing climate. He asked Dr. Summerskill whether she was satisfied that in the circumstances the powers of inspection which were available to her staff and to local authorities under the Food and Drugs Act were applied rigorously enough.

British standards of food hygiene were lower than in the United States and very bad indeed. He regretted that the model by-laws which had just been issued did not include among their excellent recommendations any reference to smoking. The preparation, handling, and serving of food should not be mixed with smoking. Customers should complain when utensils and personnel were unclean, when tea-towels were used for washing hands and cutlery and also for wiping table tops, or when washing-up water in kitchen premises was used over and over again, or when open displays of food were not properly protected from contamination.

Dr. EDITH SUMMERSKILL said that if the model by-laws recently distributed were adopted, and if the provisions made in them were carried out, it would be possible to eliminate most of these abuses. Unfortunately the public conscience was not sufficiently aroused to demand that there should be an alteration in the present practice. Outbreaks of food-poisoning were increasing; yet everyone knew that they were preventable. In fact the people had the cure in their own hands. She said that food which in the past had been thrown away was now stored, rehashed, and reheated, and so bacteria were given a new lease of life.

Mr. Skeffington-Lodge had quoted figures showing the number of cases since 1938, but he must remember that until that year food-poisoning had not been a notifiable disease. Only since then had public health laboratories supplying data on this subject been increased from 12 to more than 50. The country was more conscious of food-poisoning than in the days before 1938. The Central Council for Health Education, through the local authorities, had made an important contribution to the solution of the problem. Women's organizations also had done everything in their power. She appealed to housewives, if they saw the conditions which had been mentioned, to protest at the time and not to go to that shop again.

Salaries of Specialists

On November 1 Mr. CARMICHAEL asked the Secretary of State for Scotland if he knew of the decision of the Western Regional Hospital Board to increase the salaries of certain members of the medical staff, in some cases by more than 100%.

Mr. WOODBURN replied that the Western Regional Hospital Board had taken no such decision. They had recently made contracts with the doctors working in their hospitals providing for payment in accordance with the nationally agreed scales. These scales were settled by agreement between the Government and the medical profession last June and were [illegible] the recommendations of the Spens Report. From that it were based on and accepted by the Government with effect, which was published hospital authorities in the [illegible]nt in principle in June, 1948. All observe these nationally agr[illegible] National Health Service had to board had any discretion [illegible] scriptioned scales. No regional hospital cam[illegible]tion in the matter.

UNIVERSITY OF OXFORD

Corrected announcement

In a Congregation held on October 13 the following medical degrees were conferred:

B.M.—J. G. Widdicombe, E. A. D. W. Simpson, R. W. Torrance, *Nina A. Cohen.

*In absence.

UNIVERSITY OF CAMBRIDGE

In a Congregation on October 15 the degree of M.A. was conferred on Frank George Young, D.Sc., F.R.S., Sir William Dunn Professor of Biochemistry in the University. Professor Young has been appointed a member of the Council of the School of Veterinary Medicine until December 31, 1950, in place of Dr. Chibnall, who has resigned.

The Raymond Horton-Smith Prize for 1948–9 has been awarded to John Rupert Squire, M.D., for his essay on "The Relationship Between Horse Dandruff and Horse Serum Antigens in Asthma." *Proxime accessit:* Michael Braithwaite Paul, M.D., whose subject was "Thoracoscopy and Internal Pneumolysis in the Treatment of Pulmonary Tuberculosis."

UNIVERSITY OF LONDON

A special University Lecture on "Some Problems of Old Age" will be delivered by Dr. J. H. Sheldon at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C., on Tuesday, December 1, at 5.30 p.m. The lecture is addressed to students of the University and to others interested in the subject Admission is free, without ticket.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly comitia of the College, held on October 27, with the President, Lord Moran, in the chair, Dr. E. C. Dodds, F.R.S., was elected Harveian Librarian, and Dr. C. F. T. East, Dr. N. B. Capon, Sir Horace Evans, Dr. J. G. Scadding, and Dr. T. F. Fox were elected Councillors.

The following were elected representatives of the College: Dr. C. M. Hinds Howell on the Committee of Management of the Conjoint Board; Dr. F. S. Langmead on the Central Midwives Board; the President, Sir Leonard Parsons. Dr. H. E. A. Boldero, Dr. W. G Barnard, and Sir Allen Daley on the Standing Joint Committee of the three Royal Co[illegible] Dr. Hinds Howell, Dr. T. C. Hunt, Dr. J. C [illegible] Hawksley, and Dr. J. B. Harman on the Committee of Reference; and Dr. Hinds Howell and Dr. Harman on the Central Medical War Committee.

Dr. J. C. Broom was appointed Milroy Lecturer for 1951, his subject being "Leptospirosis."

The President announced that the Jenks Memorial Scholarship had been awarded to Barry Reid Wheeler, late of Epsom College.

MEMBERSHIP

The following candidates, having satisfied the Censors' Board were elected Members of the College:

J. D. Aitchison, M.B., L. S. Antonoff-Lewis, M.B., P. E. Baldry, M.B., T. B. Binns, L.R.C.P., M. I. Bostock, B.M., D. P. Bowler, M.B., R. E. Britten Jones, M.D., P. H. Buxton, M.B., L. Capper, M.B., R. A. Chambers, B.M., D. Collins, M.B., Geraldine E. L Cummins, M.B., R. R. De Mowbray, B.M., Captain, R.A.M.C., M. F. J. Donnelly, M.D., Margaret D. D. Dudley-Brown, M.B., J. Dundas, M.D., M. Y. El-Gammal, M.B., D. G. Evans, M.B., P. H. Friedlander, M.B., R. McK. Fulton, M.B., W. F. M. Fulton, M.B., J. M. Gardiner, M.D., I. Gordon, M.B., K. G. Green, M.D., R. Greenwood, M.B., J. H. Gubbin, M.B., D. B. Gunasekara, M.B., K. J. Gurling, M.B., E. J. Halliday, M.B., G. P. Hallwright, M.B., W. S. Hamilton, B.M., R. M. Hardisty, M.B., H. W. Holland, M.B., J. G. Holmes, M.B., Mary C. Holt, M.B., J. A. Irwin, L.R.C.P., A. D. M. Jackson, M.B., G. A. Jackson, L.R.C.P., S. L. O. Jackson, M.B., R. N. Johnston, M.B., H. E. M. Kay, M.B., R. J. Kernohan, M.D., J. D. S. Knight, M.B., D'A. Kok, M.B., M. H. Lessof, M.B., N. A. Lewtas, M.B., H. M. Lloyd, B.M., H. E. Magee, M.B., I. A. Magnus, M.B., R. H. Marten, B.M., F. B. Meade, M.B., J. B. Mitchell, M.D., J. K. Morgan, M.B., B. Mullally, M.B., N. A. Neville, B.M., L. L. Nussbaum, M.B., J. S. Oldham, B.M., D. N. Patel, M.B., R. A. Peebles Brown, M.B., E. R. Price, M.B., D. A. Pyke, M.B., J. Rankin, M.D., R. M. E. Seal, M.B., P. H. Shorthouse, L.R.C.P., Major, R.A.M.C., R. G. Simpson, M.D., A. L. Speirs, M.B., P. G. Swann, M.D., W. P. Sweetnam, M.D., M. G. Thorne,

'LOREXANE' CONCENTRATE

THE NEW PARASITICIDE FOR PEDICULOSIS CAPITIS

'Lorexane' Concentrate contains in solution 1% of the pure gamma isomer of benzene hexachloride (the active constituent of 'Gammexane' products), a powerful parasiticide.

Diluted with four parts water, it produces a fine suspension which is highly effective against pediculosis capitis, and does not irritate or harm the scalp.

A single application is sufficient to eradicate head-lice. One teaspoonful of 'Lorexane' to a tablespoonful of water is usually enough to cover the scalp.

'Lorexane' Concentrate is odourless, clean, pleasant to handle, and easily prepared for use.

Issued in containers of 50 and 500 c.c.

Literature and further information available, on request, from your nearest I.C.I. Sales Office — London, Bristol, Birmingham, Manchester, Glasgow, Edinburgh, Belfast and Dublin.

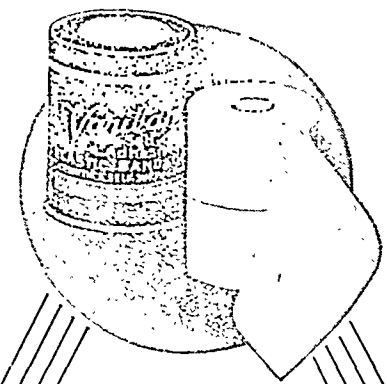
IMPERIAL CHEMICAL (PHARMACEUTICALS) LIMITED

A subsidiary company of Imperial Chemical Industries Limited

WILMSLOW, MANCHESTER



Ph.20

Why 'Ribena' in Blood Dyscrasias?

Because it is established that vitamin C is an important factor in the proper utilization of iron by the body, and that, in the treatment of iron-deficiency anaemias, an optimal intake of vitamin C is important. Because, too, clinical experience has proved its value as an adjunct in nutritional anaemias, as also in haemorrhagic states. More specific information will be gladly supplied on request.

Ribena is the pure undiluted juice of fresh ripe blackcurrants with sugar, in the form of a delicious syrup. Being freed from all cellular structure of the fruit, it will not upset the most delicate stomach. It is particularly rich in natural vitamin C (not less than 20 mgm. per fluid ounce) and associated factors.

The Successful Treatment of
FIBROSITIS
and certain cases of
RHEUMATISM
with
NOVUTOX

A mass of evidence has accumulated to show that the treatment of Fibrositis and certain cases of Rheumatism with Novutox injections provides not only complete restoration of function with immediate relief from pain, but also, in many cases, early recovery.

Interested members of the medical profession are invited to write for a copy of a Thesis on "THE INJECTION TREATMENT OF FIBROSITIS—with special reference to: Lumbago, Muscular Rheumatism (Acute and Chronic), Muscular Pain (of Traumatic Origin)."

NOVUTOX is available in:
2-oz. and 20-oz. Bottles: ½%, 1%, and 2% Solutions.
Boxes of 12 x 2 c.c. Ampoules: 1% and 2% Solutions.

Each c.c. of Novutox 2% contains 0.02 gm. ethocaine hcl., 0.00002 gm. epinephrine and 0.00002 gm. caprylhydrocupreinotoxin hcl. Other strengths of Novutox contain these elements (with or without epinephrine) in varying proportions.

DIPLOMAS

Diplomas in Child Health, in Industrial Health, and in Physical Medicine were granted jointly with the Royal College of Surgeons of England to the successful candidates whose names were printed in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of October 22 (p. 935).

Diplomas in Ophthalmic Medicine and Surgery were granted jointly with the Royal College of Surgeons of England to J. H. Owen-Flood and to the other successful candidates whose names were printed in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of October 22 (p. 935).

Diplomas in Tropical Medicine and Hygiene were granted jointly with the Royal College of Surgeons of England to T. H. Work and to the other successful candidates whose names were printed in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of October 22 (p. 935).

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College held on November 1 with the President, Dr. W. D. D Small, in the chair, a Diploma of Fellowship was granted to Dr. J J. R. Duthie (Edinburgh).

Diplomas of Membership were granted to Drs. J. H. Wright (Glasgow), W. H. Jopling (Rhodesia), T. S. Row (India), P. C. Mitchell (Aberdeenshire), R W. Crocket (Glasgow), R B. Baird (Uganda), W. H. Perry (Vancouver), J E A Bartlet (Edinburgh), D. A. Gordon (London), R. F. Maggs (Capetown), H. N. Singh (India), P. C. Bhattacharjee (India), W. D Munro (Edinburgh), B. Mukharji (India), G. I Robertson (Stirling), W. J. Weston (New Zealand), M. W. M. Hadley (Edinburgh), M. J. Murray (New Zealand), K. S. Millingen (Sydney), J. N. Pohowalla (India), K. R. Keay (Anstruther), D. F. Gibbs (Edinburgh), A. M. Rudolph (Johannesburg), and Mary D. Smith (Glasgow).

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 22. [No. 42

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

¶ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications in the week-ended October 29 were: poliomyelitis 347 (385), polio-encephalitis 20 (29). Figures for the previous week are shown in parentheses. This is the second week in which notifications have fallen.

In the following counties multiple cases were reported: London 55 (66), Bedford 2 (3), Berkshire 3 (6), Buckingham 4 (1), Chester 10 (8), Cumberland 2 (2), Derby 2 (5), Devon 3 (0), Dorset 3 (3), Durham 2 (3), Essex 26 (32), Gloucester 9 (12), Hereford 2 (0), Hertford 9 (6), Kent 16 (26), Lancaster 32 (25), Leicester 3 (13), Lincs, Lindsey 13 (7), Middlesex 17 (19), Norfolk 5 (8), Northumberland 2 (9), Nottingham 8 (9), Oxford 2 (1), Rutland 2 (1), Somerset 11 (10), Southampton 13 (13), Stafford 3 (12), East Suffolk 2 (1), Surrey 14 (16), East Sussex 9 (2), West Sussex 3 (2), Warwick 8 (9), East Yorks 2 (3), North Yorks 2 (3), West Yorks 50 (47), Glamorgan 7 (6).

Discussion of Table

In *England and Wales* there were decreases in the notifications of whooping-cough 41, acute pneumonia 37, acute poliomyelitis 33, polio-encephalitis 16, and dysentery 25, with increases in the incidence of scarlet fever 65 and measles 60.

The rise in the notifications of scarlet fever was contributed by the southern section of the country, while in the northern section there was a small fall in incidence. In the south-eastern and south-western counties a rise of 58 was recorded.

The largest rises in the incidence of measles were 44 in the Isle of Ely and 53 in Lincolnshire; the two chief centres of infection were Chatteris U.D. 57 and East Elloe R.D. 58. In the remainder of the country the trend of measles was unchanged.

The chief feature of the notifications of diphtheria was an increase of 7 in Durham. Only small variations occurred in the notifications of whooping-cough, notably decreases in Lancashire 32 and London 25.

Of the 18 cases of paratyphoid fever 12 were notified in Lancashire (Liverpool C.B. 6). A further 98 cases of dysentery were notified from the outbreak in Lancashire (Liverpool C.B. 28, Ince in Makerfield U.D. 21, Hindley U.D. 17, Abram U.D. 15); the only other important centre of infection was Glamorganshire 14 (Cardiff C.B. 10).

In *Scotland* there were decreases in the incidence of acute primary pneumonia 44 and whooping-cough 15. A fall of 13 was reported in the number of notifications of dysentery in Glasgow. Another 4 cases of paratyphoid B were notified in Lanark county.

In *Eire* there were increases in the notifications of scarlet fever 50, whooping-cough 13, and measles 11. The chief centres for scarlet fever were Dublin C.B. 70, Sligo, Sligo U.D. 12; for measles Waterford C.B. 32, Kilkenny, Kilkenny U.D. 30; and for whooping-cough Dublin C.B. 17 and Wexford, New Ross R.D. 16.

In *Northern Ireland* increases were recorded in the notifications of scarlet fever 15, whooping-cough 14, and measles 11. These trends were mainly influenced by the experience of Belfast C.B.

Statistical Review for 1947

According to Part II, Civil, of the Registrar-General's Statistical Review for 1947 the birth rate during the year at 20.5 per 1,000 total population was the highest rate since 1921. The marriage rate remained high at 18.6 per 1,000. Divorces were almost double the previous year's total, and 60,190 decrees nisi were made absolute during 1947 compared with a yearly average of 8,288 for the ten years 1936–45.

Week Ending October 29

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,972, whooping-cough 749, diphtheria 101, measles 995, acute pneumonia 303, cerebro-spinal fever 26, acute poliomyelitis 347, acute polio-encephalitis 20, dysentery 139, paratyphoid fever 14, typhoid fever 7, food-poisoning 130.

Medical News

Physicians to the King

Sir Horace Evans and Dr. D. T. Davies have been appointed Physicians to the King's Medical Household.

G.M.C. Election

Dr. O. C. Carter, of Bournemouth, has been elected a Direct Representative for England of the General Medical Council in place of the late Dr. John Bone. His term of office will be for five years, from November 8, 1949.

International European Society of Haematology

The Second International Congress of Haematology was held at Montreux on September 15–17. The presidents Drs. P. Chevallier, of Paris, P. Lambin, of Brussels, and G di Guglielmo, of Naples, welcomed haematologists from most European countries. Great Britain was represented by a small group, and Dr. W. Dameshek brought the greetings of the International Society of Hematology from the U.S.A. The secretarial work and the arrangements were in the hands of Dr. S Moeschlin, of Zurich. The first day's discussion, on the haemolytic anaemias, was introduced by Professor Heilmeyer, of Freiburg, and Dr. Dameshek, of Boston, U.S.A. Antimitotic and cytostatic substances were considered, and a discussion was opened by Professor A. Haddow with a new hypothesis on the mode of action of nitrogen-mustard. Dr. L. M. Meyer of Brooklyn, U.S.A., reported experience with folic acid and antagonists and mentioned especially his disappointment with aminopterin. Professor K. Rohr, of Zurich, finally pleaded for the continued maintenance of the classical terminology of blood cells, to which most people had become accustomed. Various demonstrations included phase-contrast photographs and marrow, liver, spleen, and lymph-gland biopsies.

Annual Meeting of University College Hospital

The annual meeting of University College Hospital was held in the Medical School on November 1. The chairman of the board of governors, Major-General Sir Harold Wernher G.C.V.O., explained that it had been decided to hold the customary meeting in public since the introduction of the National Health Service. He said that the hospital now had supervision of St. Pancras Hospital, where 300 new beds with nurses' accommodation had recently been opened. The Tropical Diseases Hospital was also under their control. The beds in the private block had been reduced during the period under review in order to afford more accommodation for the nursing staff, and the out-patient department had been modernized. Sir Harold remarked that the National Dental Hospital, which was part of University College Hospital, had been overloaded with work since the advent of the Health Service, but the efficient teaching of undergraduates was being safeguarded. He added that the working of the Act had proceeded smoothly in the University College Hospital Group, but that costs had risen considerably, particularly in the last few weeks—for example food bills had increased in price by 10%, and an extra £3,000 a year would have to be spent on streptomycin alone.

Memorial to Dr. Slome

Tributes were paid to the work of the late Dr. Irving Somerset Slome at a ceremony on October 26 at the London School of Chiropody when a memorial plaque was unveiled. Mr. R. Y. Paton, the present Director of Studies and President of the School's Governing Council, introduced Mr. R. W. Raven. Mr Raven said that Dr. Slome had been one of the best teachers of anatomy in London. He had done a great deal in seeking the co-operation of hospitals in connexion with the training of students in chiropody. Mr. A. M. A. Moore, President of the Board of Registration of Medical Auxiliaries, then unveiled the plaque, and described how Dr. Slome, a South African by birth,

had been one of the most brilliant students at the London Hospital, where he qualified in 1935. His death at the early age of 36 was a great loss.

Homoeopathic Hospital Centenary

The London Homoeopathic Hospital marked its centenary by a reception on November 2 in the Great Hall of the British Medical Association, Tavistock Square. The King, who is patron of the hospital, sent a message, and the reception was attended by the Duke and Duchess of Gloucester who were received by Mr. A. Clifton Brown, chairman of the management committee, and Sir John Weir, honorary consulting physician to the hospital. The Duchess was presented by a member of the nursing staff with a bouquet compounded of 50 varieties of flowers and plants from all of which homoeopathic drugs are regularly prepared. The hospital was established in 1849 by the English Homoeopathic Association in a small house in Golden Square. It comprised only 25 beds. In 1857 the freehold of the fine property at the corner of Great Ormond Street and Powis Place was acquired, and the new building was opened on May 12, 1857, the Lord Ebury of that day giving the inaugural address. The eastern part of the hospital is on the site of a house where Macaulay spent the years of his early manhood and wrote the first of his famous essays. It is intended further to mark the centenary by an appeal for funds to carry on homoeopathic research, education, and practice.

Cigarettes for the Disabled at Christmas

The Alexandra Musical Society is arranging to send boxes of cigarettes to disabled ex-Servicemen in hospitals, convalescent homes, sanatoria, and mental hospitals on Christmas Day. This scheme has been made possible through the generosity of the Rhodesia Tobacco Association. Medical superintendents or matrons who have not already applied for their hospitals to be included in the scheme should write at once to Mr. Ernest C. Thomas, Honorary Organizing Secretary, Alexandra Musical Society, Room 412, County Chambers, Martineau Street, Birmingham. The gifts are only for the disabled ex-Servicemen who will be patients in hospital on Christmas Day. The society also hopes to entertain 1,000 disabled ex-Servicemen at various Christmas parties. To enable these events to be carried out an appeal is made for £500. Donations will be greatly welcomed and appreciated. Her Majesty the Queen has honoured the society with a donation towards its work for disabled ex-Servicemen.

British Rehabilitation Methods in Greece

On a visit to Greece in March this year, which was arranged by the British Council in collaboration with the British Medical Association, Mr. St. John Buxton, senior orthopaedic surgeon at King's College Hospital, and Mr. A. E. Whiffing, technical inspector to the Ministry of Pensions limb-fitting centre at Roehampton, gave advice to Greek hospitals and artificial limb factories on British methods. The co-ordinating committee of the Greek Recovery Programme has now invited them to return, their expenses being paid by the Economic Co-operation Administration. Mr. St. John Buxton will leave for Athens on November 16 to give further advice on rehabilitation and to deliver lectures on orthopaedic surgery, and Mr. Whiffing has been seconded for three months to the co-ordinating committee to reorganize the artificial limb factories.

Wills

Dr. Brian Ingram Johnson, pathologist at Churchill Hospital, Oxford, who died in a car accident on March 19, left £50,043. Dr. James Barr, of Torquay, left £37,500; Dr. Robert Anderson, of Edgbaston, Birmingham, £13,310; and Dr. William Forbes McDonald, of Bristol, £1,194. Mr. Edgar Somerville, of Newton Abbot, Devon, left £40,976; Dr. James Galbraith, of Dingwall, £42,783. Professor John McGibbon, of Crieff, who was emeritus professor of midwifery and gynaecology, University of St. Andrews, left £5,249; Mr. Arthur Herbert Buck, of East Dereham, Norfolk, £4,391. Mr. Owen William Richards, of Bideford, Devon, formerly director of the Egyptian Government School of Medicine, left £72,109.

COMING EVENTS

Institute of Laryngology and Otology

Professor Geoffrey Jefferson, F.R.S., will deliver the annual address at the Institute of Laryngology and Otology, 330–332, Gray's Inn Road, London, W.C., on Friday, November 18, at 4.30 p.m. His subject is "The Acoustic Neuromas."

Liverpool School of Tropical Medicine

A reception will be held at the Liverpool School of Tropical Medicine, Pembroke Place, Liverpool, on Tuesday, November 22, at 7.45 for 8.15 p.m., on the occasion of the fiftieth anniversary of the opening of the school and presentations of the Mary Kingsley Medal.

Society of Medical Officers of Health

The annual dinner of the Society of Medical Officers of Health will be held at the Piccadilly Hotel, London, W., on Thursday, November 24, at 7 for 7.30 p.m.

Leeds School of Medicine

The fifty-ninth annual dinner of the past and present students of the Leeds School of Medicine will be held at the Great Northern Hotel, on Friday, November 25, at 7 for 7.30 p.m., when Professor J. W. McLeod, F.R.S., will preside. Professor H. S. Raper, F.R.S., Dean of the Faculty of Medicine of the University of Manchester, will be the guest of honour. Tickets may be obtained on application to the honorary secretary, at the Medical School, Leeds.

National Association for Mental Health

A one-day inter-clinic conference of the professional staff of child-guidance teams will be held at the Y.W.C.A. Central Club (Queen Mary Hall), Great Russell Street, London, W.C., on Saturday, December 3. The fee for admittance to the conference is 5s. (2s. 6d. for full members of the association), and applications should be sent to the conference secretary, Inter-clinic Conference, National Association for Mental Health 39, Queen Anne Street, London, W.1.

Conference on Psychology

A conference on "The Outlook for Psychology" will be held at the Oxford House, Mape Street, Bethnal Green Road, London, E.2, on Sunday, December 4, starting at 10.30 a.m. Among the speakers will be Dr. W. Lindesay Neustatter, on "Psychology in the Clinic." Particulars may be obtained from the Oxford House.

Manchester Medical Ball

The Manchester Division of the B.M.A. and the Manchester Local Medical Committee have arranged a medical ball to be held at the Midland Hotel, Manchester, on Wednesday, December 7, when there will be a dinner at 7.30 p.m. and dancing until 1 a.m. Tickets (£1 5s. each) may be obtained from Dr. F. S. Catto, B.M.A. Regional Office, 33, Cross Street, Manchester, 2.

SOCIETIES AND LECTURES

Monday

LONDON UNIVERSITY.—At University College (Chemistry Theatre), Gower Street, London, W.C., November 14, 5.15 p.m., "*The Chemistry of the Transuranics and Other Newly Discovered Elements*," by Professor H. J. Emeléus, F.R.S.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, Cavendish Square, London, W.—November 14, 8.30 p.m., Discussion: "*Medico-Biopsies*," to be introduced by Dr. R. Bodley Scott and Dr. R. B. Terry.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—November 14, 4.45 p.m., "*Bacterial Toxins*," by Dr. W. E. Van Heyningen.

Tuesday

EUGENICS SOCIETY.—At Royal Society, Burlington House, Piccadilly, London, W., November 15, 5.30 p.m., "*Family Service Units for Problem Families*," by Mr. David Jones.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Postgraduate Medical School of London, Ducane Road, W., November 15, 3 p.m., "*Radiotherapy in Treatment of Uterine Malignant Disease*," by Mr. Malcolm Donaldson.

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—November 15, 5 p.m., "*Psoriasis*," by Dr. F. R. Bettley.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, London, S.W.—November 15, 5 p.m., "*Devices for the Protection of the Worker Against Injury and Disease*," Ernestine Henry Lecture by Dr. Donald Hunter.

ROYAL PHOTOGRAPHIC SOCIETY: MEDICAL GROUP.—At 16, Princes Gate, London, S.W., November 15, 7 p.m., "*The Importance of Quality in Medical Photography*," by Mr. E. V. Willmott, F.R.P.S.

Wednesday

HARVEIAN SOCIETY OF LONDON.—At 26, Portland Place, London, W., November 16, 8.15 p.m., "*Oesophageal Disorders in Children*," by Dr. W. P. H. Sheldon.

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—November 16, 5 p.m., "*X-ray Technique*," by Dr. C. W. McKenny.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Clare Hall Hospital, South Mimms, Barnet, November 16, 3 p.m., meeting.

NORTH EAST LONDON CLINICAL SOCIETY.—At Prince of Wales's Hospital, Tottenham, N., November 16, 8 p.m., films and discussion on antenatal and obstetric subjects.

ROYAL INSTITUTE OF PHILOSOPHY.—At University College (Anatomy Theatre), Gower Street, London, W.C., November 16, 7.30 p.m., "*Hume and Kant and Their Attitude to Metaphysics*," by Mr. P. F. Strawson.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—November 16, 3.30 p.m., "*Hygiene in the Factory*," by Dr. J. J. O'Dwyer.

ROYAL MICROSCOPICAL SOCIETY, B.M.A. House, Tavistock Square, London, W.C.—November 16, 5.30 p.m., ordinary meeting. "*Cytology of the Neurone in Experimental Poliomyelitis*," by Dr. G. M. Findlay and Mr. F. C. Grigg.

SOCIAL PSYCHOTHERAPY CENTRE, 7, Fellows Road, London, N.W.—November 16, 5 p.m., "*Active Psychotherapy*," by Dr. A. R. Redfern.

Thursday

BRITISH INSTITUTE OF RADIOLOGY.—At 32, Welbeck Street, London, W., November 17, 8.15 p.m., joint meeting with Section of [illegible] *Chemical Factors Modifying Radiobiological Response*," to be opened by Dr. John Read.

DURHAM UNIVERSITY.—At Royal Victoria Infirmary, Newcastle-upon-Tyne, November 17, 5.15 p.m., "*The Study of the Living Cell*," Rutherford Morison Lecture by Dr. Arthur Hughes.

HONYMAN GILLESPIE LECTURE.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, November 17, 5 p.m., "*The Surgical Management of the Malignant Colon*," by Mr. G. T. Mowat.

ROYAL MEDICAL SOCIETY.—At Royal College of Physicians of Edinburgh, Queen Street, Edinburgh, November 17, 7.15 for 7.30 p.m. President's annual dinner.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., November 17, 7.30 p.m., laboratory meeting.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—November 17, 4.30 p.m., lecture-demonstration: "*Neurology*," by Dr. D. J. Williams.

WESTMINSTER HOSPITAL SCHOOL OF MEDICINE, Meyerstein Lecture Theatre, Horseferry Road, London, S.W.—November 17, 5.30 p.m., clinico-pathological demonstration. Discussions; (1) "*Osteitis Fibrosa Cystica*," (2) "*Asthma*."

Friday

BRITISH INSTITUTE OF RADIOLOGY.—At 1, Wimpole Street, London, W., November 18, 8.15 p.m., joint meeting with Section of Radiology, R.S.M., "*Chemical Factors Modifying Radiobiological and Radiotherapeutic Response*," to be opened by Drs. Frank Ellis and L. A. Elson.

BRITISH TUBERCULOSIS ASSOCIATION.—At 26, Portland Place, London, W., November 18, 3.15 p.m., Presidential address: "*Tuberculosis Services in the Future*"; "*Tuberculosis Survey in Malaya*," by Dr. Andrew Morland; "*Tuberculosis Survey in Western Samoa*," by Dr. Brian Thompson.

FACULTY OF RADIOLOGISTS: THERAPY SECTION MEETING.—At Royal College of Surgeons, Lincoln's Inn Fields, London, W.C., November 18, 2.15 p.m., "*Modern Conceptions of a Dosage Unit for Radiotherapy*," by Dr. L. H. Gray.

INSTITUTE FOR THE SCIENTIFIC TREATMENT OF DELINQUENCY.—At St. George's Institute, Broadbent Street, Davies Street, London, W., November 18, 5 p.m., annual general meeting and address by the Earl of Feversham.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330–332, Gray's Inn Road, London, W.C.—November 18, 4.30 p.m., "*The Acoustic Neuromas*," by Professor Geoffrey Jefferson, F.R.S., annual address.

MAIDA VALE HOSPITAL FOR NERVOUS DISEASES MEDICAL SCHOOL, Maida Vale, London, W.—November 18, 5 p.m., clinical demonstration by Dr. D. McAlpine.

ROYAL INSTITUTE OF PHILOSOPHY, 14, Gordon Square, London, W.C.—November 18, 5.15 p.m., "*Everything*," by Mr. H. L. A. Hart.

ROYAL SANITARY INSTITUTE, 90, Buckingham Palace Road, London, S.W.—November 18, 2.30 p.m., "*The New Milk (Special Designations) Regulations*," discussion to be opened by Dr. W. A. Lethem (Ministry of Food).

UNIVERSITY COLLEGE, Gower Street, London, W.C.—November 18, 5.15 p.m., "*Transmission of Excitation in Nerve and Muscle*," by Dr. Bernhard Katz.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At South Kensington Hotel, 41, Queens Gate Terrace, London, S.W., November 18, 7.15 for 7.30 p.m., dinner meeting. "*The Story of Cortisone*," by Dr. W. S. C. Copeman.

Saturday

YORK MEDICAL SOCIETY.—At 17, Stonegate, York, November 19, 8.30 p.m., "*Ascertainment and Educational Treatment of Deafness*," by Professor A. W. G. Ewing and Mrs. Ewing.

APPOINTMENTS

CRAWSHAW, DONALD G., M.B., Ch.B., D.C.H., D.P.H., Medical Officer of Health, Peterborough.

DAVIES, J. O. F., M.D., D.P.H., D.R.C.O.G., Senior Administrative Medical Officer, Oxford Regional Hospital Board.

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—*Assistant Chest Physician (Senior Registrar) in Cambridge Area*, J. B. Mitchell, M.D. *Assistant Chest Physician (Senior Registrar) in East Norfolk Area*, P. H. Sutton, M.D., M.R.C.P.

LYON, D. M., M.B. Ch.B., D.P.H., Deputy County Medical Officer of Health and Deputy School Medical Officer for Kent.

SOUTH WESTERN REGIONAL HOSPITAL BOARD.—The following appointments have been announced. *Geriatrician, Bristol Clinical Area*, W. Hughes, M.D., M.R.C.P., D.T.M. *Assistant Plastic Surgeon, Frenchay Hospital, Bristol*, D. C. Bodepham, M.B., Ch.B., F.R.C.S.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cooper.—On October 15, 1949, at Southmead Hospital, Bristol, to Flavia Cooper (née James), M.B., Ch.B., D.A., wife of Ashley Cooper, a second daughter—Caroline.

Piney.—On October 29, 1949, to Gladys (née Fleet), wife of Dr. J. Piney, a son.

MARRIAGE

Watson—Lowis.—On October 10, 1949, at Dunleer, Co. Louth, Eire, John Ernest Watson, M.B., B.Ch., to Margaret Sarah Lowis.

DEATHS

Bergin.—On October 25, 1949, at Clifton, Bristol, Frank Gower Bergin, M.R.C.S., L.R.C.P.

Brown.—On November 2, 1949, in London, John Claude Brown, M.D., of 16, Addison Gardens, London, W.

Burnett.—On October 7, 1949, Arthur Hill Burnett, M.R.C.S., L.R.C.P., of Bitterne Park, Southampton, aged 68.

Curry.—On October 28, 1949, at his home in Towning Place, Cross Hills, Keighley, Yorks, Alexander Curry, L.R.C.P.&S.I.

Davis.—On November 5, 1949, at a nursing-home, the Rev. George Brocklesby Davis, M.D., of 371, Cherry Hinton Road, Cambridge, formerly of C.M.S., India, and Ely, Cambridgeshire, aged 76.

Debono.—On October 12, 1949, Salvino Debono, M.D., of Malta.

Eason.—On November 2, 1949, at Nuffield House, Guy's Hospital, Sir Herbert Lightfoot Eason, *C.B., C.M.G.*, M.D., M.S., F.R.C.S., aged 75.

Fairbairn.—On October 31, 1949, at 1, St. Mary's Grove, London, S.W., Donald Charles Fairbairn, M.C., M.B., B.S.

Ferraby.—On November 1, 1949, at 140, Broomfield Avenue, Worthing, Sussex, George Arthur Ferraby, M.R.C.S., L.R.C.P.

Lake.—On November 1, 1949, in a Bristol nursing-home, Richard Lake, F.R.C.S., aged 87.

Macdonald.—On October 29, 1949, at Edinburgh, Coll Macdonald, M.B., Ch.B., of Westcliff-on-Sea, Essex.

Macdonald.—On November 2, 1949, at 9, Fernielan Avenue, Edinburgh, Angus Macdonald, M.B., C.M., F.R.C.S.Ed., late of Southdean, Colinton Road, Edinburgh.

Muir.—On October 29, 1949, at Lealands, Box, near Stroud, Gloucestershire, Joseph Corbett Muir, M.D.

Nixon.—On November 4, 1949, at Forbes Fraser Hospital, Bath, John Hobart Nixon, M.D., of 25, Deansway, Chippenham, Wilts, aged 72.

Palmer.—On October 31, 1949, at Exmouth, Cadwallader Edwards Palmer, M.B., B.Ch., Colonel I.M.S., Ret., aged 68.

Palmer.—On October 19, 1949, at Torquay, Sydney Joseph Palmer, M.B.E., M.D.

Price.—On November 2, 1949, at a nursing-home, Leamington Spa, Horace John D'Arcy Gerard Price, M.R.C.S., L.R.C.P., formerly of Nuneaton, Warwickshire, aged 68.

Pridmore.—On November 3, 1949, at 5, The Terrace, Chale, Isle of Wight, John Walter Pridmore, M.R.C.S., L.R.C.P., late of Ryde, Isle of Wight, aged 79.

Rogers.—On October 28, 1949, in London, Norman Cumming Rogers, M.B., Ch.B., of 3, St. John's Wood Road, London, N.W.

Roper.—On October 17, 1949, at a nursing-home in Rochester, Kent, Charles Roper, M.D., D.P.H., aged 71.

Russell.—On October 26, 1949, at Southport Infirmary, John Cooper Russell, M.B., Ch.B., of 33, Balfour Road, Southport, Lancs.

Sevestre.—On October 13, 1949, at 38, Springfield Road, Leicester, Robert Sevestre, M.D., J.P., *aged 81*.

Shelley.—On October 12, 1949, at St. Bartholomew's Hospital, Rochester, Arnold Shelley, M.B., B.Ch., of Camden House, Chatham.

Shipton.—On October 31, 1949, at Briarfield, Milford-on-Sea, Hants, William Shipton, M.D., J.P., of Buxton, Derbyshire.

Watson.—On October 15, 1949, at 21, The Circus, Bath, Andrew Gordon Watson, M.D.

Young.—On October 25, 1949, at Torwood, Tomintoul, James John Taylor Young, M.D., aged 84.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Treatment of Retinitis Pigmentosa

Q.—*Is there any effective treatment of retinitis pigmentosa? Has there been any further work published on the implantation of preserved placenta, which I believe was suggested by Filatov?*

A.—The inquirer must have referred to four articles which appeared in the Journal of Soviet Medicine, 1946, 3, No. 5: "The Treatment of Pigmentosa with Intramuscular Injections of Placenta" (p. 388); "Retinitis Pigmentosa and the Question of Preserved Placenta in Retinitis Pigmentosa" (p. 398); "The Implantation of Preserved Living Tissues in Pigmentosa" (p. 398)—all by V. P. Filatov and N. Nazarova. There was also an article by Von Max Nowakowski in Ophthalmologica, 1948, 116, No. 4-5, 241-249 on the Placentatherapie der Retinitis Pigmentosa which might be consulted.

Placental implants beneath the conjunctiva for retinitis pigmentosa are being carried out in this country, but no one is yet in a position to give a firm opinion about the value of this treatment. The feeling among certain Continental surgeons is that temporary subjective improvement occurs in some cases but that the visual field is not increased. No statements are made about slowing or checking the progress of the disease. Filatov's facts are not carefully set out in his papers on this subject. Oestrogens and cervical sympathectomy have also been tried but without any appreciable effect. The writer's impression to date is that the claims made for all the therapeutic measures tried for retinitis pigmentosa are unconvincing.

Mortality from Bovine Tuberculosis

Q.—*I have seen it stated in the Press that bovine tuberculosis accounts for about 1,500 deaths per annum in England and Wales. Is there any statistical evidence to support this statement?*

A.—There is no statistical evidence, in the usually accepted meaning of the term, to support this statement. The number of deaths from bovine tuberculosis is an estimate based on a series of necropsies where bacteriological examination has been carried out in fatal cases of non-pulmonary tuberculosis to determine whether the infection was of human or of bovine origin. In 30% of the cases the origin was found to be bovine. In some of the fatal cases of respiratory tuberculosis the infection is, of course, also of bovine origin. From the evidence available the number of deaths due to the bovine type of disease has been calculated as one-third of the deaths from non-pulmonary tuberculosis. During the last three years for which the figures of deaths from non-pulmonary tuberculosis in England and Wales are available a large decrease has been reported. Deaths from non-pulmonary tuberculosis in the years 1946-8 numbered 3,482, 3,394, and 2,897, respectively. It is therefore likely that 1,500 deaths per annum is an overestimate of the present level of mortality from bovine tuberculosis.

Stilboestrol and Dysmenorrhoea

Q.—*Can prolonged administration of stilboestrol cause dysmenorrhoea? For the last four months a young woman has been treated for acne on her face by 0.5 mg. of stilboestrol dipropionate twice a day during the second week of the intermenstrual period. The condition of the skin has improved, but lately the patient has complained of dysmenorrhoea on the first day, otherwise her periods are normal. Are there any known ill effects of indefinitely continued treatment?*

A.—Stilboestrol, even in heavy and prolonged dosage, does not directly cause dysmenorrhoea. If given during the first half of the cycle in amounts large enough to inhibit ovulation it prevents dysmenorrhoea, because oestrogen-withdrawal haemorrhage is always painless. In the case quoted the dose is hardly enough to prevent ovulation—it might even be stimulating it in a woman who has previously had anovulatory cycles, and this would explain the onset of painful periods. On the other hand, the onset of dysmenorrhoea is more common at this age than at the menarche, and it may be unrelated to the treatment. Although the continuous administration of oestrogens has side-effects such as endometrial hyperplasia, irregular and heavy uterine haemorrhage, and pigmentation of the nipples, the intermittent treatment described is unlikely to do harm even if continued for several months.

Estimation of Erythrocyte Sedimentation Rate

Q.—*Could you give me an authoritative opinion on the correct procedure for estimating the erythrocyte sedimentation rate (Westergren method)? My own technique is as follows: To 0.5 ml. of 3.8% sodium citrate is added 2 ml. of fresh blood. The tube is set up immediately and read after one hour. Frequently two tubes are set up simultaneously, as I find that slightly different readings are obtained from each. The points I would like elucidated are: (1) Why do different readings occur? (2) Should the blood be allowed to reach room temperature before the tube is set up? (3) Should flocculation occur in the 3.8% solution of sodium citrate? (4) If slightly less than 2 ml. of blood is used, in what manner is the reading affected?*

A.—The questioner's procedure is identical with that of the writer, and is preferable to the method described in the answer in the *Journal* of March 17, 1945, because it is very difficult to fill a 2-ml. syringe without introducing air-bubbles, thus making an erroneous dilution. To take the questions seriatim: (1) In duplicate estimations variations of up to 10% should be expected, because it is impossible to set tubes exactly vertical and deviations of as little as one degree from the vertical should make an appreciable difference. (2) This is probably unimportant. Thermal equilibrium with the surroundings will be reached very quickly after the blood has been drawn up into the tube, which should not be in a draught or in a place where rapid changes of temperature occur. If duplicate estimations are made at different temperatures, considerable differences in readings occur. (3) No. If gross agglutination or flocculation occurs, then either the blood has started to clot or the patient is suffering from gross hyperglobulinaemia, the commonest cause of which in this country is myelomatosis. If, however, the question is intended to imply that flocculation occurs in the citrate without the addition of blood, then this should not normally occur; when it does it is nearly always due to the growth of fungal mycelium. This may be overcome by sterilizing the citrate in 25-ml. batches in universal containers and throwing away the contents as soon as they cease to be crystal clear. (4) The writer cannot answer this question, but believes that errors of 10% have surprisingly little effect.

Phonocardiography

Q.—*What exactly is phonocardiography, and has it any special advantages? Is it possible to make gramophone records of the heart sounds?*

A.—Phonocardiography is the graphic registration of heart sounds and murmurs. Its chief clinical advantage is that it provides a permanent record of the auscultatory findings. But it has other advantages: (1) it may resolve auscultatory doubts; (2) it serves to time heart sounds and murmurs against other electrical or mechanical events which may be recorded simultaneously; (3) it has proved helpful in analysing the nature of the heart sounds. Unfortunately, phonocardiograms are difficult to perfect technically, and many records being obtained at the present time are not entirely reliable. Again, the simultaneous recording of other events which aid the interpretation of the records presents other difficulties and necessitates more elaborate equipment. For this reason phonocardiography is unlikely to be used widely in this country for many years. Most cardiological units and research departments, however,

are studying it. Henriques made gramophone records of the heart sounds which could be played back to an audience. The results were poor, sounds and murmurs being grossly distorted and interference being considerable. His machine met with little enthusiasm in this country, and so far as is known is not being made now. It could certainly not be recommended for didactic purposes; auscultation could never be learnt from this device.

Post-herpetic Neuralgia

Q.—*Is there any method of preventing post-herpetic neuralgia? What domiciliary treatment can be used for this complication? Are injections of liver extract and vitamin B of value?*

A.—The prevention of post-herpetic neuralgia in the elderly appears to depend on treatment during the active stage of the zoster infection. The hypodermic injection of 0.5 ml. of pituitrin daily for 21 days from the onset of the infection has always proved successful in the experience of the writer. Large doses of vitamin B_1 by injection, sodium iodide by mouth, and more recently the antihistamines have also been used with some success.

"Allergy" and "Hypersensitivity"

Q.—*Can you distinguish between allergy and hypersensitiveness? To a question on lipstick dermatitis (July 16, p. 189), in which the inquirer talks about allergy, the answer carefully avoids the term and refers to hypersensitiveness. Is there any proof of hypersensitivity to the eosin colouring matter in lipsticks? Eosin belongs to the fluorescein series, and these substances are used, for example, on the conjunctiva for diagnostic purposes. Are there any corresponding cases of hypersensitivity to fluorescein?*

A.—Some years ago writers on this subject considered allergy and anaphylaxis as subdivisions of the main subject—hypersensitiveness. Allergy was often defined as hypersensitiveness occurring in man. At the present time the tendency is to consider anaphylaxis as a subdivision of the main subject—allergy—and hypersensitiveness becomes synonymous with "allergic state." Whichever terminology is used, "hypersensitiveness" is interchangeable with "allergy" or "allergic state" so far as human reactions are concerned. It is merely a question of using the term which the writer considers more generally acceptable in this country. Apart from this, "hypersensitiveness" is sometimes used in a wider sense than the word "allergy," which implies, at least, an antigen–antibody reaction in the tissue cells. Thus a person might be described as hypersensitive to misuse of the word "allergy," but not as allergic to it. The conservative mode of thought in this country is perhaps reflected in a continued preference for the word "hypersensitiveness," as distinct from the Americans' ready acceptance of the shorter and neater "allergy."

Proof of hypersensitivity to the eosin colouring matter in lipsticks has been obtained—see Sulzerberger, Goodman, Byrne, and Mallozi, *Arch. Derm. Syph., Chicago*, 1938, 37, 597—and is now generally accepted. The writer has not come across any reference to fluorescein sensitivity.

Cancer of Bladder in Dye Workers

Q.—*What is the incidence of bladder carcinoma among aniline workers? Has aniline ever been held responsible for cancer in any other sites? An aniline worker, a patient of mine, has developed an osteosarcoma of the humerus with multiple bone secondaries and involvement of the chest.*

A.—Bladder tumours are known to occur among a high proportion of workers in the aniline dye industry, but they are not in general attributable to aniline as such. The substances generally held to be responsible are amino derivatives of naphthalene and benzidine. Such tumours have been observed and recorded in many different countries, including America, Russia, Japan, and the principal countries manufacturing aniline dyes in Europe. The actual incidence is not known, since many workers leave the factories before the tumour has developed and are not traceable. However, it is held by various observers that where working conditions are unsatisfactory almost all the workers in the department may be attacked, but at different times and in different forms. Very occasionally the kidney is also involved.

Primary tumours in other sites than the bladder and kidney cannot be attributed to work with dyestuff intermediates. The disease has been known for some 55 years, but no suggestion has ever been made that such tumours as bone sarcoma occur more frequently among workers in dye intermediates than among the general population. Experimental evidence exists that other amino derivatives of cyclic hydrocarbons can produce primary tumours in other sites—for example, liver, stomach, as well as bladder—but there is no evidence that such tumours arise in workers as an industrial disease.

Persistent Monilia Infection

Q.—*Two male patients have persistent monilia infection of the oral cavity. Treatment with aniline dyes, aluminium acetate, and vitamins has been most unsatisfactory, and reference to numerous books offers little encouragement. Can you advise?*

A.—Persistent monilia infection of the oral cavity usually suggests an unhealthy condition of the mucous membrane, since it is generally thought that moulds will not grow where the mucous membrane is healthy. In the majority of cases attention to cleanliness is the most important measure. In persistent cases where the condition does not disappear with attention to oral hygiene a search for possible systemic causes should be made. The disease is frequently associated with deficiency of vitamin-B complex, and in such cases large doses coupled with intramuscular liver injections may prove beneficial. The condition is also occasionally seen in diabetics, and it is therefore advisable to exclude any diabetic tendency. For local application gentian violet is, of course, the standard treatment, but silver picrate preparations are equally effective and do not have the undesirable staining properties of the aniline dyes. Boric acid solutions are of little value.

NOTES AND COMMENTS

Acute Nephritis and Sweating.—Dr. CHARLES ROMER (Worcester) writes: From time to time the answers in "Any Questions?" must have surprised your readers and have made them wish that the replies were not anonymous. In the *Journal* of October 1 (p. 767) the hardy annual of whether to nurse a case of acute nephritis in blankets is revived. As the General Nursing Council still expects this (together with an intimate knowledge of leeches, wet and dry cupping, etc.) is it not time, Sir, to ask that the subject should be thrashed out and a really authoritative statement issued? Your answer states: "The General Nursing Council is acting in this matter with the full approval of medical authority. The scientific principle involved is allied to the known fact that patients suffering from this disease tend to sweat excessively." The answer continues very logically that such patients are more comfortable in blankets, and for rheumatic fever everyone is in agreement. No mention is made of the diaphoretic action, which must be taken as approval of such measures being, as Dunlop and Davidson in their *Textbook of Medical Treatment* (1949, Edinburgh) put it, "now generally abandoned." The crux of the matter is, then, do patients with acute nephritis "tend to sweat excessively"? No mention of such sweating is made in Price, Savill, Sheldon, Paterson, or Ellis's Croonian Lectures (*Lancet*, 1942, 1, 34 and 72). None of the medical sisters asked, nor the writer, can recall having seen this alleged sweating. It is of interest to think that there can be such a wide divergence of opinion over a point that can be settled by simple clinical observation. The writer can see no reason for continuing to use blankets, but would beg for really authoritative views, lest another baby be thrown away with the bath water.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY NOVEMBER 12 1949

THE SECRETARY REPORTS

MEDICAL SUPERINTENDENTS

For as long as the National Health Service lasts the medical profession will have its grievances, some of them large and others small. But I doubt whether it will ever have a more strongly grounded grievance than its objection to the terms and conditions of service of future medical superintendents. The area of the grievance may be small, in that the number of persons affected is not large. None the less, a regrettable state of affairs exists.

Consider first the medical superintendent who is a specialist. The broad plan is that he should be remunerated as a specialist for that part of his time he spends on specialist duties and as an administrator for the remainder, unless the amount of time spent on administration is trivial. It will be observed that, if the administration element is not trivial, his remuneration will be lower than that of any member of his staff, possibly his deputy, who is engaged whole-time or almost whole-time on specialist duties. Here then is the first grievance—that it should be possible for a specialist medical superintendent to receive less remuneration than a specialist deputy medical superintendent or a specialist medical officer who is neither a superintendent nor a deputy.

The wind has been tempered, however, in the case of a medical superintendent of a mental hospital. The Ministry has made plain in an official circular that his administrative work "need not, it is estimated, exceed 10% of the time given by a whole-time officer, and this may properly be regarded as so small a proportion of the time that there need be no abatement of the remuneration at clinical rates for the whole of his time." Incidentally, in the assessment of clinical duties they are taken to include "activities directly connected with the treatment, training, and occupation of patients, as well as general supervision of entertainments and the provision of amenities." In other words, the authorities classify some non-clinical work as clinical and then give a broad hint that the remaining administrative work can be regarded as *too small in amount to justify reduction* in salary. This is reasonable and sensible. But why not extend this kind of definition and assumption to all medical superintendents whether of mental hospitals or not?

A greater grievance arises where the amount of administrative time is more than trivial, constituting the whole or part of the time. At its worst, the whole-time medical superintendent of a large hospital is regarded for purposes of pay, and so of status, as exactly the same as the lay secretary of a hospital management committee. This means remuneration somewhere between £640 and £1,700 inclusive, the actual remuneration being determined on a points system.

Purely Administrative Posts

Existing officers have, of course, some protection. The test of the position will arise when a post for a purely administrative medical superintendent falls vacant and the hospital authority invites applications from medical practitioners to fill it. It is insisted that a doctor is needed. All the authority will be permitted to offer is the salary applicable to a lay secretary. The Ministry seems to have the idea that there is only one variety of administration, and whether it is done by doctor or layman it is just the same and should be paid for at the same rates. It is entirely wrong that where a doctor is needed for a purely administrative post he should be paid as a layman and not as a doctor. Some may think that it is desirable that we should move away from medical administration to lay administration, but that is a question of policy which it would be wrong to mix with questions of remuneration. If a doctor is wanted he should be paid as a doctor.

This Ministry attitude to the whole-time administrative superintendent affects the salaries of all future holders of posts involving both clinical work and administration, except where the time spent on administration is trivial. We recently had an example of the application of the terms of service in a particular case. An advertisement was received from the South-west Metropolitan Regional Hospital Board for a medical superintendent at the St. Mary's Hospital, Portsmouth, a hospital of 1,039 beds, in the following terms:

> Applications are invited by the Board for the whole-time appointment of
>
> MEDICAL SUPERINTENDENT
>
> The successful candidate will be required to undertake the medical administration of the hospital, and his duties will include the medical care of nursing staff, charge of chronic sick wards, three sessions per week to be devoted to clinical surgery, superintendence of mental deficiency beds, and the control of admissions and discharges. The salary for medical duties (six sessions) will be based on the scale £1,300 by £50 to £1,750 per annum and for administrative duties (five sessions) on the appropriate administrative scale—i.e., £710 by £25 to £910 per annum. Living accommodation will be provided, in respect of which a charge will be made. The appointment will be subject to the provisions of the National Health Service (Superannuation) Regulations, 1947, and will be in accordance with the agreed terms and conditions of service of hospital medical and dental staff under the National Health Service. Applications, stating age, qualifications, experience and present appointment, and giving the names and addresses of three referees, should be made by letter and sent to the Secretary (S.D.1), South-West Metropolitan Regional Hospital Board, 11a, Portland Place, London, W.1, to arrive not later than September 17, 1949. Canvassing will disqualify.

The composite salary approximates to a scale of £1,032 to £1,368, subject to deduction for accommodation. This is an illustration of the application of the Ministry's formula, as it conforms to the terms of service. The salary is far too low for the work and responsibility involved.

Clinicians have not always loved medical administrators, but they will, I think, agree to two propositions. The first is that they should pause awhile before expressing an official view as to the form administration should take in the future in the hospital field. Preference for lay administration might conceivably be replaced, in the light of experience, by one for medical administration. The second proposition is this: the profession should insist that, wherever there is a job which a doctor only can fill, even though it be administrative in character, the pay should be such as is appropriate to a doctor. That there *is* such a thing as medical administration—as distinct from lay administration—no doubt the medical officers of the Ministry of Health and our colleagues in the public health service would agree, however difficult the lay administrator may find it to accept that a medical training contributes something to certain kinds of administration which their own training does not.

SOCIAL SECURITY IN WESTERN UNION

The Foreign Ministers of the five Brussels Treaty Powers—Belgium, France, Luxembourg, the Netherlands, and the United Kingdom—have signed two conventions linking arrangements for social security in the five countries.

The first convention, which is related to the bilateral agreements on social security already negotiated or being negotiated between the five countries, will enable nationals of these countries to take advantage of any of these agreements no matter in which of the five countries they reside or have resided. The benefits covered by these agreements include those provided in case of sickness, invalidism, old age, death, maternity, industrial injuries, and prescribed occupational diseases.

Free Medical Treatment

The second convention is based on the principle that if a national of any of the five countries, when resident in the territory of any of the other four, requires social or medical assistance, but is without sufficient resources, he will receive such assistance from the latter country on the same basis as its own nationals. For example, an Englishman living in Holland, who is without sufficient resources, will receive the same free hospital treatment as a Dutchman in similar circumstances.

The five countries will not reimburse each other for the cost of any such assistance. Repatriation solely on the ground that assistance is likely to be long-continued or costly is not to be resorted to if the person concerned has, for instance, close family ties in the foreign country in which he is living or has resided there for more than five years—10 years if he entered that country after the age of 55—or is not in a fit state to be transported. But the convention does not affect the ordinary laws governing repatriation on other grounds.

A supplementary agreement is to be worked out between the Governments dealing with a number of matters of detail.

APPOINTMENTS TO HOSPITAL MANAGEMENT COMMITTEES

The terms of office of about one-third of the members of hospital management committees expire on March 31, 1950. The members will be eligible for reappointment for a further term of three years. The Minister of Health considers that it is "the intention of Parliament and clearly desirable" that there should be full consultations on this matter, even though the N.H.S. Act does not require the regional hospital board to consult any body specified except the committee itself. This view is expressed in Circular R.H.B. (49) 143 from the Ministry of Health.

Balanced Membership

The Minister's aim is to have on each committee a balanced membership, including the appropriate types of experience and reflecting the interests of the community to be served. When members are due to retire from management committees, boards should inform the following bodies of the retirements and invite them to submit suggestions: the committee itself; every local health authority and every executive council any part of whose area is served by the committee; senior medical and dental staff of each of the hospitals concerned; and each of the bodies originally consulted under paragraph (*d*) of Part 2 of the Third Schedule of the Act, together with any other local bodies which appear to the board to be appropriate.

A reasonable proportion of the retiring members may be reappointed, but boards should consider introducing some new element into the membership—e.g., from house committees or from the local community.

Community Interests

The proportion of professional members should not be high. "The committee must essentially be and remain a group of non-professional members of the local community rendering voluntary service in the public-spirited tradition of the past and in the interests of the community."

Officers of committees should not be appointed as members of them, though there is less objection to appointing officers of one committee to be members of another. Members of both management committees and hospital boards should be strictly limited.

Doctors and matrons should be invited to attend meetings of management committees and their subcommittees. They can make their fullest contribution to the work of the committees by attending as advisers rather than as members.

CHEMISTS PROTEST AGAINST 1/- TAX

The Pharmaceutical Society has informed the Prime Minister that the charge of up to 1s. on prescriptions will not deter those who are misusing the Service to a serious extent, though it will tend to reduce calls on the services of doctors and chemists under the Service. "It would appear that the charge will be prejudicial to the use of the Service by persons who need medical attention, but will not reduce excessive and unnecessary resort to doctors and chemists by those who are least deserving of the benefits they are receiving."

COLLIERY MEDICAL OFFICERS

Members of the Joint Subcommittee on Remuneration of National Coal Board Medical Officers, and 19 representatives of part-time colliery medical officers from various areas, attended a conference on October 26 under the chairmanship of Dr. I. D. Grant.

The first discussion ranged round rates of pay proposed by part-time medical officers and approved by the Representative Body at Harrogate. The conference agreed that this scale should be accepted.

Discussion followed on the duties of part-time colliery medical officers, the issue being whether such practitioners wished to be an integral part of the Colliery Medical Service or merely available for emergencies in their area. It was pointed out that although area medical officers were appointed they were not normally, owing to distance, available for emergencies. It was finally agreed that the duties of part-time colliery medical officers should be as laid down in the duties of industrial medical officers.

Emergency Calls

Fees for emergency calls were then considered, and emergency calls were divided by the conference into three categories:

(1) Where the casualty is available at the pit-head when the doctor arrives or very shortly afterwards.
(2) Where the doctor is required to go underground.
(3) Where the doctor has to wait at the pit-head for the casualty to be brought up.

It was suggested that in the last two categories fees should be on the basis of £1 11s. 6d. an hour or part of an hour.

The question of benefits payable by the National Coal Board where a doctor is injured or killed while attending at a mine was referred to the Joint Subcommittee.

Recommendations were made to the Joint Subcommittee regarding payment for examination of outstanding colliery compensation cases and also regarding co-option of certain members of the conference on to the subcommittee.

NATIONAL INSURANCE LOCAL ADVISORY COMMITTEES

Nominations Invited from Local Associations by November 30

The Minister of National Insurance, Mr. James Griffiths, is setting up 230 committees to advise on questions relating to the local administration of the National Insurance Act; 186 of these committees will be in England, 26 in Scotland, and 18 in Wales. Each committee will consist of about 20 members, of whom six will represent employers and six employees. There

will be two or three representatives of local authorities and one or two of friendly societies. These representatives will be called together and asked to select four or five other persons with suitable local knowledge to complete the full committee.

The Ministry of National Insurance local associations wishing to nominate such persons for consideration should put forward their names, with particulars of their qualifications, not later than November 30 to the appropriate *regional controller* of the Ministry of National Insurance.

National Insurance Regions

The areas covered by each National Insurance region and the address of the regional controller are shown in the following table

Region	Area Covered	Address of Regional Controller
Northern	Northumberland, Cumberland, Durham, Westmorland, and North Riding of Yorkshire	Newcastle-upon-Tyne
East and West Ridings	West Riding and East Riding of Yorkshire	5–7, New York Road, Leeds, 2
North Midlands	Derbyshire, Nottinghamshire, Lincolnshire, Leicestershire, Rutlandshire, and Northamptonshire	Block 3, Government Buildings, Chalfont Drive, Western Boulevard, Nottingham
Eastern	Huntingdonshire, Cambridgeshire, Norfolk, Suffolk, Bedfordshire, Essex, and Hertfordshire	"St. Regis," Montague Road, Cambridge
Inner London	Area of London County Council and County of Middlesex	31, Cumberland Terrace, London, N.W.1
Outer London	Surrey, Kent, Sussex, and parts of Hertfordshire and Essex	2–12, Prince Albert Road, Regent's Park, London, N.W.1
Southern	Oxfordshire, Buckinghamshire, Berkshire, Hampshire, Isle of Wight, and Dorsetshire	Whiteknights Park, Earley, Reading, Berks
South Western	Gloucestershire, Wiltshire, Somersetshire, Devonshire, and Cornwall	"Avonleigh," Stoke Park Road South, Bristol, 9
Midland	Herefordshire, Shropshire, Staffordshire, Warwickshire, and Worcestershire	Broadway Court, 69, Broad Street, Birmingham, 15
North Western	Counties of Cheshire, Lancashire, and the High Peak District of Derbyshire, viz., Bamford, Buxton, and Glossop, New Mills, and Chapel-en-le-Frith	"Heyscroft," Palatine Road, Didsbury, Manchester, 20
Wales	Wales and Monmouthshire	Cathays Park, Cardiff
Scotland	Scotland	39, Drumsheugh Gardens, Edinburgh, 3

EMERGENCY BED SERVICE

The work of the Croydon Emergency Bed Service was taken over on November 7 by the South-western Branch of the E.B.S., Gap Road, Wimbledon (telephone: Wimbledon 6581).

The following functions, formerly carried out by the Croydon Bed Service, are now the responsibility of the Croydon Group Hospital Management Committee at Croydon General Hospital (telephone: Croydon 3427): chronic-sick and pay-bed accommodation admissions to Croydon hospitals, and admissions to Coombe Cliff Convalescent Home.

Particulars of other E.B.S. offices were listed in the *Supplement* of October 8 (p. 160).

TREATMENT OF MERCHANT SEAMEN IN PORT

Executive councils are responsible for arranging medical treatment for merchant seamen on shore (*Supplement*, August 13, p. 80). The Ministry of Health has now issued a circular on the provision of drugs and appliances when prescribed for these seamen by doctors employed whole-time by the Shipping Federation at the London and Royal Docks and the ports of Southampton, Cardiff, Manchester, Newcastle-upon-Tyne, Liverpool, and Glasgow.

A special issue will be made to these practitioners of Forms E.C.10 bearing the name of the London Executive Council and stamped "Shipping Federation Medical Officer." These prescriptions may be handed in at pharmacies in the area of any executive council, even though the practitioners are working in the various ports named.

HOSPITAL STAFF DISMISSED

The general practitioner staff of the North Herts and South Beds Hospital at Hitchin have received notices of dismissal as from October 31. The staff point out that their dismissal is contrary to the Minister's intentions expressed in circular R.H.B. (49) 132 (*Supplement*, October 15, p. 168), which warns regional hospital boards that they are not to deprive patients of hospital beds in the charge of general practitioners. The hospital staff have taken up the matter with the Minister of Health.

HEARD AT HEADQUARTERS

Hearing-aids

From a discussion at the Medical Society of London the other day we gather that the difficulties which have surrounded the introduction of the Government hearing-aid are being smoothed out. The bottle-neck is no longer at the distribution centres, where it used to be, but in the diagnostic clinics. It was stated that it is extraordinary how many old people are thrilled when, after a little instruction, they get the "hang" of the thing—people who, a few years ago, would never have thought of trying such an appliance. On the other hand, some of them cannot put up with these electrical contrivances, and the old ear trumpet or the "banjo" still has its vogue. We were told of old people who sit on either side of the fireplace and communicate with one another through three feet of rubber tube. One speaker knew of someone who has already had five Government hearing-aids. His complaint is that after about two months some fault in the material declares itself, and the aid has to be taken back and a new one obtained while the old one is repaired and renovated. It was suggested that it would have been more economical for the Government to use less cheap material.

Rendezvous

One lady to another in a doctor's waiting-room: "Ah, Mrs. Smith, I haven't seen you here lately. I hope you haven't been unwell."

Questions Answered

Salary of Hospital Locum

Q.—*I have been qualified for two years and have just finished a B2 appointment. Without having been graded I have been appointed locumtenent to an assistant medical officer who is on special leave. The doctor I am replacing was graded as registrar from July, 1948. Pending the new hospital establishment he has been receiving his original (lower) salary. What remuneration am I entitled to expect?*

A.—The Ministry has instructed boards of governors, regional boards, and hospital management committees that a locumtenent engaged to fill the post of house officer, J.H.M.O., or registrar shall be remunerated at the same rate as the officer whose place he is filling. In this case, as the grade of the officer whose work the locum has taken over is that of registrar (first year), the salary to which he is entitled is £775 per annum.

Refusal of Temporary-resident Patients

Q.—*Am I not entitled to refuse to have temporary residents on my list and to charge them private fees?*

A.—A doctor is free to refuse to accept a person on his list, either as a temporary or a permanent patient; but he must (*a*) give any person who has applied for and been refused acceptance by him advice on the steps to be taken to enable him to be accepted by another doctor, and (*b*) provide without charge to the patient any treatment required by the person in an emergency or pending acceptance by another doctor.

CENTRAL CONSULTANTS AND SPECIALISTS COMMITTEE

REPRESENTATION OF CONSULTANTS

At the meeting of the Central Consultants and Specialists Committee held at B.M.A. House on November 3, with Mr. R. L. Newell in the chair, a letter from members of the South-west Metropolitan (Western Area) Regional Committee, which appeared in the *Supplement* of October 22 (p. 185), was considered. The letter complained of the decision of the Central Committee that the Joint Committee should appoint and instruct the members of the staff side of the Whitley Council, and stated that the Regional Committee had decided unanimously that if the Central Committee continued to be subordinated to the Joint Committee the Regional Committee would consider withdrawing its representatives from the former and relying on representation by other means.

The chairman deplored the publication of such a letter. He restated the views set forth in his own reply, published in the *Supplement* of November 5 (p. 206). He said that the letter from the Regional Committee was in many ways misleading. If any constituent body represented on the Joint Committee had written such a letter he would have regarded it as a disastrous action. The Joint Committee had worked very well indeed and had the confidence of the Ministry. It had never been in disagreement with any of its constituent bodies. In fact, there had never been a division on any question. He felt that if the Regional Committee persisted in its demand the result would be that consultants would be represented by many bodies without any real authority whatsoever, instead of by one body to which the Ministry now looked as representing the consultants of the country. The chairman's remarks were received with expressions of general assent.

Mr. Ross Smith, one of the signatories of the letter, said that it was complained particularly that no reference was made to the regional committees before it was decided to subordinate the Central Committee to the Joint Committee in the matter of the representation of hospital medical staffs. He and his fellow signatories could not agree that the Joint Committee should be the instructing body. The instructing body should be a committee democratically elected. One matter on the present agenda concerned the setting up of an independent fighting fund for hospital medical staffs. It would surely be an anomalous position if the Central Committee acted as the defence organization, holding the defence fund in trust, while another body over which it had at best only minority control had to decide action. He could not see the general body of consultants in this country having confidence in such a set-up, and if there was not confidence there would not be financial support.

The Secretary (Dr. Charles Hill) said that other bodies wanted to participate in representation on Whitley Councils. The Central Committee was set up to speak for the general body of consultants, and the Joint Committee was established in order to avoid the possibility of half a dozen separate organizations each claiming an independent right. If there was a departure from that collective position they might be represented on the Whitley machinery by the three English Colleges, the Scottish Colleges or Corporations, by their own committee, possibly by the British Medical Association as a separate organization, and other bodies, and would be in a worse position. It was of paramount importance to consultants and specialists to have for Whitley purposes one generally accepted body.

Other members expressed regret at the lack of trust in the Joint Committee which was made evident in the letter. On the other hand, one member suggested that the Central Committee had been set up on a sufficiently broad basis to include almost all the bodies which were entitled to be considered by the Ministry.

After a short discussion it was agreed that the letter from the Regional Committee be left to lie on the table.

Special Distinction Awards

Dr. Rowland Hill, chairman of the Executive Committee, presented certain proposals as a basis for discussion on the assessment of "merit" for distinction awards. It was recommended that "merit" be defined as the total professional value of a consultant to the community, and that the following factors be taken into consideration in the assessment: the nature and responsibility of posts held and the standard of efficiency attained in the performance of the duties of the posts; professional qualifications and academic and other professional attainments; and the value of the consultant's researches and his published works.

The committee also submitted certain amended proposals as to the method of implementation. One of these was that lists of recipients of merit awards should not be published in the medical or lay press, but should be made available to the profession by the National Committee, which decided the awards, through the Joint Committee and its constituent bodies and by boards of governors and regional boards to their medical committees and medical advisory committees respectively, all such information to be regarded as confidential.

Dr. Rowland Hill pointed out that with most awards a reasonable degree of publicity was part of the award, and it was significant of the atmosphere which surrounded the whole of this arrangement that such secrecy had to be observed. He added that it was not the advertising of the recipient which was to be deprecated, but the "de-advertising" of those whose names did not appear in the list.

The difficulty of maintaining secrecy about the awards was mentioned in the committee, especially the difficulty of disclosing something to the profession and withholding it from the public. One member advocated the fullest publicity for the awards, if only in order that young consultants might know at what objectives to aim.

The committee agreed generally with the proposals put forward, including the one that in each region there should be established a committee of distinguished practitioners of consultant status, not interested in merit awards (that is, those already in receipt of the highest award or retired from practice), who should select consultants in the area for recommendation to the National Committee. It was the general feeling that the Central Committee should not itself participate in the recommendations.

Pay-bed Accommodation

Some discussion took place on the continuing reduction in the number of private hospital beds and the increase in maintenance charges. Dr. Rowland Hill said that the question would be further discussed with the Ministry, and particulars of any hard cases would be submitted. It was stated that there was a drive to create amenity beds out of private beds. It was agreed to press the point that the retention of private hospital beds at an adequate level would reduce the cost of the hospital and specialist service.

Various recommendations from groups were considered. One of them, from the Venereal Diseases Group Committee, urged that regional hospital boards be asked to make facilities available for the training of women as specialists in venereology, with a prospect of adequate employment and the opportunity of competing for the highest honours in the specialty. It was also asked that arrangements should be made for women patients who so desired to be treated by women venereologists. This was endorsed by the committee for representation to the Ministry.

The Radiologists Group Committee asked that the question of financial assistance to radiologists to offset the loss of capital due to the fact that their practices had become unsaleable should be taken up. It was agreed that this question should be one of the items to be considered by the Whitley Council as soon as it was formed.

The committee reappointed its six representatives on the Joint Committee—namely, Dr. T. Rowland Hill, Mr. C. E. Kindersley, Dr. W. S. Mack, Mr. A. M. A. Moore, Mr. R. L. Newell, and Mr. T. Holmes Sellors.

Correspondence

Status of General Practice

SIR,—The rape of general practice has been going on for some long time, but its progress has been accelerated by the introduction of the new National Health Service. By "rape" I mean to convey the taking away from the general practitioner of what is now considered outside his competence and handing such sections of his work over to the specialist, so often a side of his work which he considers the most interesting. Among the early branches of practice that went in this way were ophthalmology, dentistry, pathology, and public health. Later this was followed by orthopaedic and E.N.T. work, anaesthetics, and the staffing of clinics for children and antenatal purposes. At the present time the process is being completed by removing from the competence of the general practitioner the general surgery previously carried out by him as a member of the staff of his local hospital.

The reason given is the increase in newly acquired medical knowledge and its constantly changing techniques. This has been exploited far too fully, so that now the general practitioner has the practice of nearly all techniques (complicated or comparatively simple) removed from him, if not on the ground that they are considered outside his competence, then included in a neat bundle with those which quite possibly are. This, in the future, must tend to produce a deterioration in the type of practitioner for what is the object of learning to become proficient along certain special lines if in the future there will be no opportunity of putting such into practice? Why choose to become a house-surgeon if, after leaving the hospital, you will never remove an appendix or perform any routine surgical procedures?

The rights and wrongs of the present tendency are debatable, but what is not debatable is the fact that the status of the general practitioner must be maintained, so that what was described by a professor of medicine as "the backbone of the profession" should not become the resort of the comparative failures within the profession, swayed and governed by the body of specialists, who, however brilliant in their own sphere, often dismally fail to comprehend medical practice in anything like its breadth and depth.

It should remain the main object and the grave responsibility of all teaching hospitals to create as in the past a body of general practitioners capable of carrying out successfully the routine techniques of the department in which they serve after qualification. It is these men who should serve the needs of the smaller local hospitals in the areas in which they later find themselves.

In the present chaotic over-organization of doctors' work by other doctors the outstanding results appear to be on one side the unmanageable weight of work thrown upon the specialist and the hospital in which he works, and on the other side the general practitioner increasingly divorced from the more technical and stimulating sides of his work, striving to retain at least some interest in his professional work, from which so much other than the hack work has been successfully removed.—I am, etc.,

Long Handborough, Oxford. CLEMENT J. L. WELLS.

SIR,—The slogan of the Church of England's Mission to London to be read on the posters stated that "Recovery starts from within," a truth inherent not only in things spiritual but a truth very widely neglected. Does the medical profession give due weight to the fact that recovery starts from within? I see little evidence of its doing so. We discuss rates of pay, grading of specialists, and so on, while giving little attention to the reorganization of the medical services. The original B.M.A. health scheme did little more than suggest that the dependants of N.H.I. patients should be added to the doctors' panels, as though the panel system was in itself the answer to the demand for an improved medical service.

Improved rates of pay will not ensure a satisfactory medical service. The importance of the general practitioner must be fully recognized and not merely paid lip service to, and he must be, as he is not at present, fully trained for his work, which in many respects differs from that of the consultant and specialist. Health centres are not needed primarily to do away with doctors' surgeries but to provide diagnostic and treatment facilities for general practitioners.

Many of the regulations are a direct insult to general practitioners. They are now informed that they may no longer in an emergency obtain direct an oxygen tent, but must do so through a hospital consultant, who alone may order belts, valgus pads, and such simple things. If the general practitioner is as inefficient as all that, something is seriously wrong with his medical education, for which these consultants are responsible; and will these consultants bear in mind Sir Robert Hutchison's dictum, "No one is too good to be a general practitioner."

One way of maintaining a high standard among general practitioners is to associate them with the hospitals in some semi-official way such as clinical clerkship. This could be arranged on a rota system. In America it has been noted that clinical ability tends to decline after leaving hospital and being separated from its work.

The reforms I suggest are (1) better training of the general practitioner for the work he has to do, (2) provision of diagnostic and treatment facilities, and (3) continued association of the general practitioner with the work of a hospital.

I may be wrong in these suggestions, but, bearing in mind that recovery starts from within, let us at least recognize the need for reform and strive to promote it.—I am, etc.,

London, W.8. HAROLD H. SANGUINETTI.

Protest Against Higher Pay

SIR,—In the *Sunday Times* of September 4 I was surprised to read that the B.M.A. (of which I am a member) is putting in a claim for still higher payment for general practitioners. When I was a panel doctor—1922 to 1937—the capitation fee was around eight to nine shillings, and I was quite satisfied. It was not my only source of income, any more than it is the only source of income of National Health Service practitioners to-day—private practice (and there is still quite a lot available) and part-time appointments, of which there is a wide scope (divisional police surgeons, part-time industrial medical officers, dental anaesthetics, child-welfare clinics, examinations under the Factory Acts, minor-ailment treatment centres for school-children, to mention a few). Also a number of general practitioners have specialized in ophthalmology, nose, throat, and ears, dermatology, industrial medicine, etc., and hold part-time appointments in these.

Even if a few doctors depend only on their National Health Service remunerations they appear more than adequately paid for it, and it must also be remembered that a high percentage of the medical investigation and treatment of their patients is carried out at the hospital.

I wish to protest against this demand for a further increase, which to my mind is quite unjustified. I would also remind the B.M.A. of the serious financial position of the country; but the country's interest is quite forgotten in the general scramble for more money for less work. I am sending a copy of this letter to the Minister.—I am, etc.,

London, N.6. W. A. H. BELL.

Establishment of Registrars

SIR,—It needs no more than a few moments' reflection to realize that a serious problem is fast gaining momentum. At most of the larger hospitals, especially teaching institutions, there has been an increase in the number of registrar appointments in proportion much greater than that before the war.

Ten years ago in two neighbouring hospitals there was a total of 15 registrars; to-day there are 41. These figures are typical of other centres. One large teaching hospital, at least, has multiplied its number more than 10 times.

Since the post-war replenishment of permanent appointments vacancies have now become very few, and the intended expansion of specialist services shows no sign at present of taking

place. The situation is already indicated by the large list of applicants for any staff appointment. It is a situation which is bound to deteriorate unless steps are taken, and it is a disheartening position for those who have been at pains to spend years in special training.

If the country still needs and can economically support a great specialist service, it seems that now is the time to enlarge establishments. If this is not the case, then it would be rational to limit the total number of registrars in a reasonable proportion to the number of permanent specialist appointments.—I am, etc.,

London, W.1. P. H. NEWMAN.

Compensation for Taking Partner

SIR,—One can only view the letters from principals and assistants which have been published recently with a great deal of sympathy for both sides, but also with horror that acrimony is developing within the profession itself.

Many principals would be willing, even pleased, to grant partnerships to their assistants if they could be sure that the loss of income involved could be balanced by the acquisition of capital as was the practice in pre-N.H.S. days. May I suggest that the Ministry of Health be approached to grant immediate compensation to the value of the share given to an incoming partner?

It could be stressed to the Minister that this procedure would ensure that his protégé (the penniless young doctor) obtained a professional livelihood, and that practice in general would benefit thereby.—I am, etc.,

Hayes, Kent. MATTHEW SHERIDAN.

Bifocal Glasses

SIR,—In reply to Dr. H. S. Gaskell (*Supplement*, October 22, p. 185) it should be pointed out that bifocal lenses are more difficult to obtain than single-sighted lenses, and a large increase in the proportion of bifocals prescribed would lead to very long delays. Solid bifocals, in particular, are in very short supply.

From the point of view of expense there is little difference, since the cost of two frames fitted with single-sighted lenses is approximately the same as one frame with bifocals.

Bifocal lenses are a great boon to thousands of people, but in many cases they are not suitable, and the decision must rest with the ophthalmic optician or ophthalmic medical practitioner carrying out the examination.—I am, etc.,

S. BLACK,
London, W.1 Association of Optical Practitioners.

Tax on Prescriptions

SIR,—In your annotation (*Journal*, October 29, p. 971) you remark that "Mr. Attlee's decision that a patient from now on will have to pay a small token fee up to a 1s. for prescriptions issued under the N.H.S. . . . will be welcomed by the medical profession." Before we have details of how this charge is going to be made it is extremely difficult to express a considered opinion on it. Household remedies for one patient are medical necessities for another—e.g., cotton-wool for a patient with a colostomy. Aspirins, which the Minister now suggests that the patient should buy, before the N.H.S. were sold to him by his private doctor either as tablets dyed pastel shades of pink or yellow or in the form of very palatable emulsion, coloured or plain according to fancy. One thing we can regret from Mr. Attlee's decision is that the Government has decided that the economic barrier to medical services shall be reintroduced

The responsibility of over-prescribing must lie with the doctors. Complaints that seem trivial to the medical man seem important and even dangerous to the ignorant and the neurotic. When we complain of overcrowded surgeries we are apt to forget that patients often wait for two hours for our advice and opinion. They would rarely do this if it was to save themselves 6d. for a bandage. The result of a charge for prescriptions may well mean that patients already discouraged by over-full waiting-rooms will return to self-medication and patent medicines.

Mr. Attlee and his Government have done little to help the general practitioners to run the Service. We wait in vain for the amenities of the health centres, but his latest action will not be welcomed by the general practitioner in the industrial areas, who foresees hardship for many, especially the large families of the lower income group.—I am, etc.,

Birmingham. M. BARROW.

Housing and Health

SIR,—In view of the national crisis and possible further economies in national expenditure, I feel that the medical profession should make a stand against any further reduction in the already inadequate housing programme.

It seems little use pouring money into the sacrosanct National Health Service when a steady stream of mentally ill people is also being poured into it as a result of inadequate housing. The loss to the nation in man-hours must be colossal when one considers the mental illness that is brought about by overcrowding and having to live with uncongenial relations and under unhygienic conditions. In addition to this, much time in psychological departments is given up by psychiatrists and psychological social workers to fighting a losing battle with these conditions. I say nothing of the time and cost to the nation of juvenile delinquency, largely consequent on marital breakdown due to inadequate housing.

It seems to me that the housing problem should be sacrosanct, and if this were so the needs of the National Health Service would be considerably decreased.—I am, etc.,

London, W.1. MARION GREAVES.

POINTS FROM LETTERS

Mental Change

Dr. D. SAKLATVALA (W. Bromwich, Staffs) writes: It has been "Heard at Headquarters" (*Supplement*, October 1, p. 149) that the Minister of Health is baffled by "the mental change that comes over a doctor when he functions as a member of organized medicine." In believing that there is such a change the Minister is exhibiting a mental phenomenon which is universally seen in laymen but which need not, I think, baffle us. It is a matter of common experience that Mr. Everyman has, and ever has had, complete trust in the humanity, integrity, and skill of "his own" doctor. At the same time it has long been common knowledge that doctors as a body are always under the suspicion of Mr. Everyman. The B.M.A. has for many years been scathingly spoken of as "the strongest trade union," while the man-in-the-street is never ready to believe in doctors as a class suffering any hardship or difficulty, because he can always believe that, before all else, doctors look after themselves. . . . When the patient is in trouble, then all his hopes, all his future, seems to be in the hands of his doctor, and if he is to have confidence in his future he must have confidence in his doctor. If he is to be emotionally stable this confidence must be absolute, and not weakened by any doubts. . . . The surest way of avoiding any such doubts is, clearly, to "decide" that, while Dr. A is a paragon of all the relevant virtues, Drs. B, C, D, etc., are a collection of unprintable rogues and scoundrels. . . . Since in the profession Mr. Everyman's (or Mr. Bevan's) "own" doctor is in a minority of one, while the rest are the unreliable scoundrelly nincompoops, it follows that Mr. Everyman can safely trust the one, while he *must* suspect and abhor the many. Mr. Bevan is reported as urging "psychological research." I venture to find that unnecessary, but I believe that some "public relations" research is badly needed. It has long been my view that the combating of this ambivalence in the public's attitude should be our first propaganda concern, for until we have eradicated it all our other teaching falls on stony ground. Unfortunately I have no idea of how we should begin.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar.

Non-County Borough Councils.—Dartford, Wallsend.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huyton-with-Roby, Redditch (restricted to new appointments), Tyldesley.

H.M. Forces Appointments

TERRITORIAL ARMY

ROYAL ARMY MEDICAL CORPS

Major H. F. T. Macfetridge, D.S.O., I.M.S. retired, to be Lieutenant (Substituted for the notification in a *Supplement* to the *London Gazette* dated March 15.)

Captain A. M. Rennie to be Major.

Captain K. W. N. Palmer, T.D., to be Major.

Captain D. C. Taylor has been granted the acting rank of Major.

Lieutenant G. J. Dixon to be Captain, and has been granted the acting rank of Lieutenant-Colonel.

Lieutenant D. H. Jenkins to be Captain, and has been granted the acting rank of Major.

Lieutenant R. V. Stone to be Captain, retaining the acting rank of Major.

TERRITORIAL ARMY RESERVE OF OFFICERS: ROYAL ARMY MEDICAL CORPS

Majors J. B. Schofield and J. D. Swan, from Active List, to be Majors.

REGULAR ARMY: EMERGENCY COMMISSIONS

ROYAL ARMY MEDICAL CORPS

Lieutenant (Acting Lieutenant-Colonel) A. A. W. Petrie, C.B.E., has relinquished his commission (without pay and allowances) and has been granted the honorary rank of Lieutenant-Colonel.

Captains J. G. Kendall and G. Maizels have relinquished their commissions and have been granted the honorary rank of Major.

ROYAL AIR FORCE

Air Chief Marshal P. C. Livingston, C.B., C.B.E., A.F.C., K.H.S., to be Air Marshal

Flight Lieutenants R. Mortimer, J. M. Dawson, J. J. McNair, and E. C. F. Bramwell to be Squadron Leaders.

J. B. Good to be Squadron Leader (Temporary).

ROYAL AIR FORCE VOLUNTEER RESERVE

Squadron Leader J. B. Good has relinquished his commission on appointment to a temporary commission in the R.A.F.

Flight Lieutenants R. D. McD. Morrison and K. R. Hudson have relinquished their commissions on appointment to the reconstituted R.A.A.F., retaining the rank of Wing Commander.

Flight Lieutenant G. P. Arden to be Squadron Leader.

Flight Lieutenant J. R. Anderson has relinquished his commission on appointment to the reconstituted R.A.A.F., retaining the rank of Squadron Leader.

Flight Lieutenant P. M. Lynch has relinquished his commission, retaining the rank of Squadron Leader.

WOMEN'S FORCES

EMPLOYED WITH THE MEDICAL BRANCH OF THE R.A.F.

Flight Lieutenant L. G. Moore to be Squadron Leader.

Flight Lieutenant E. H. M. Lewin has relinquished her commission, retaining the rank of Squadron Leader.

INDIAN MEDICAL SERVICE

Major-General J. P. Huban, C.S.I., O.B.E., has retired.

Lieutenant-Colonels H. W. Mulligan, T. A. Doran, C. R. Henderson, H. S. Smithwick, O.B.E., and P. H. Cummins have retired, and have been granted the honorary rank of Colonel.

Lieutenant-Colonels J. F. Shepherd, M.B.E., S. T. Davies, A. I. Cox, O.B.E., J. L. Donnelly, J. H. Gorman, B. J. Griffiths, W. J. L. Neal, O.B.E., and G. Milne have retired.

Majors N. A. Michael, F. A. B. Sheppard, C.I.E., O.B.E., and G. T. Wrafter have retired.

Captain W. W. Hamilton has retired, and has been granted the honorary rank of Major.

Lieutenants L. H. Nugent and P. G. Morris have retired, and have been granted the honorary rank of Major.

INDIAN MEDICAL DEPARTMENT

Captains K. E. R. Robertson, N. A. Michael, and N. C. Todd to be Majors.

COLONIAL MEDICAL SERVICE

The following appointments have been announced: D. F. Clyde, M.D., Medical Officer, Tanganyika; A. Hargreaves, M.B., Medical Officer, Dermatologist, Kenya; C. E. Hunter, M.D., Medical Officer, British Somaliland; M. A. Rozalla, M.B., Medical Officer, Sarawak; J. F. Nunn, M.B., Medical Officer, Federation of Malaya; Z. S. Walko, M.D., Assistant Medical Officer, St. Lucia, Windward Islands; R. L. Cheverton, M.R.C.S., Director of Medical Services, Gold Coast; H. D. Tonking, M.R.C.S., Pathologist, Nigeria; H. M. Johnston, M.B., M.P.H., Malariologist, Jamaica; E. H. Madge, M.B., Medical Superintendent, Victoria Hospital, Mauritius; M. Theodoulou, M.D., and C. C. Ioannides, M.D., District Medical Officers, Cyprus.

Association Notices

FORMATION OF ST. VINCENT BRANCH

The Council has formed a St. Vincent Branch comprising the area of the Island of St. Vincent, British West Indies.

The new Branch comes into existence as from the date of publication of this notice.

CHARLES HILL,
Secretary.

November 12, 1949.

PRIZES FOR MEDICAL STUDENTS, 1950

The Council of the British Medical Association is prepared to consider the award in 1950 of prizes to medical students for essays submitted in open competition.

The subject of the essays shall be "Clinical Teaching in Relation to the Practice of Medicine."

The purpose of these prizes is the promotion of systematic observation among medical students. In awarding the prizes due regard will be given to evidence of personal observation. No study or essay that has previously appeared in the medical press or elsewhere will be considered eligible for a prize. Any medical student who is a registered member of a medical school in Great Britain or Northern Ireland at the time of submission of the essay is eligible to compete for a prize.

If any question arises in reference as to the eligibility of a candidate or the admissibility of his or her essay, the decision of the Council of the British Medical Association shall be final. In determining the number and the value of the prizes to be awarded the Council will take into consideration the number of essays received. Should the Council decide that no essay entered is of sufficient merit, no awards will be made.

Each essay must be typewritten or legibly written in the English language, on one side of the paper only, must be unsigned, and must be accompanied by a form of application which can be obtained from the undersigned. Essays must be forwarded so as to reach the Secretary of the British Medical Association not later than December 31, 1949. Inquiries relative to the prizes should be addressed to the Secretary, British Medical Association, B.M.A. House, Tavistock Square, London, W.C.1.

NATHANIEL BISHOP HARMAN PRIZE

The Council of the British Medical Association is prepared to consider the award of the Nathaniel Bishop Harman Prize in the year 1950. The value of the prize is approximately £100. The purpose of the prize is the promotion of systematic observation and research among consultant members of the staffs of hospitals who are not attached to recognized medical schools. It will be awarded for the best essay submitted in open competition. The work submitted must include personal observations and experiences collected by the candidate in the course of his practice. A high order of excellence will be required. No study or essay that has been previously published in the medical press or elsewhere will be considered eligible for the prize.

Any registered medical practitioner who is a consultant member of the staff or senior hospital medical officer of a hospital in Great Britain or N. Ireland and is not attached to a recognized medical school is eligible to compete. If any question arises in reference to the eligibility of a candidate or the admissibility of his essay the decision of the Council shall be final.

Should the Council of the Association decide that no essay submitted is of sufficient merit, the prize will not be awarded in 1950 but will be offered again the year next following this decision, and in this event the money value of the prize on the occasion in question shall be such proportion of the accumulated income as the Council shall determine.

The writer of the prize-winning essay may be required to prepare a paper on the subject for publication in the *British Medical Journal* or for presentation to the appropriate Section of the Annual Meeting of the Association. Each essay must be typewritten or printed in the English language, and must be distinguished by a title and a motto. The essay must not bear the name of the writer, which should be sent with the essay in a sealed envelope bearing only the motto on the outside.

The title of the proposed essay and the motto should also be notified in writing to the Secretary by December 1, 1949, on a form to be

obtained from the Secretary. Essays must be forwarded to reach the Secretary, British Medical Association, B.M.A. House, Tavistock Square, London, W.C.1, not later than March 31, 1950. The prize will be awarded at the Annual Meeting of the Association to be held in 1950. Inquiries relative to the prize should be addressed to the Secretary.

SIR CHARLES HASTINGS CLINICAL PRIZE

The Sir Charles Hastings Clinical Prize, which consists of a certificate and a money award of 50 guineas, is again open for competition. The following are the regulations governing the award:

1. The prize is established by the Council of the British Medical Association for the promotion of systematic observation, research, and record in general practice.
2. Any member of the Association who is engaged in general practice is eligible to compete for the prize.
3. The work submitted must include personal observations and experiences collected by the candidate in general practice, and a high order of excellence will be required. If no essay entered is of sufficient merit no award will be made. It is to be noted that candidates in their entries should confine their attention to their own observations in practice rather than to comments on previously published work on the subject, though reference to current literature should not be omitted when it bears directly on their results, their interpretations, and their conclusions.
4. Essays, or whatever form the candidate desires his work to take, must be sent to the British Medical Association House, Tavistock Square, London, W.C.1, not later than December 31, 1949. The prize will be awarded at the Annual General Meeting of the Association to be held in 1950.
5. No study or essay that has been published in the medical press or elsewhere will be considered eligible for the prize, and a contribution offered in one year cannot be accepted in any subsequent year unless it includes evidence of further work. A prizewinner in any year is not eligible for a second award of the prize.
6. If any question arises in reference to the eligibility of the candidate or the admissibility of his or her essay the decision of the Council on any such point shall be final.
7. Preliminary notice of entry for this competition is required, on a form to be obtained from the Secretary.
8. Each essay must be typewritten or printed, must be distinguished by a motto, and must be accompanied by a sealed envelope marked with the same motto and enclosing the candidate's name and address.
9. The writer of the essay to whom the prize is awarded may, on the initiative of the Science Committee, be requested to prepare a paper on the subject for publication in the *British Medical Journal* or for presentation to the appropriate Section of the Annual Meeting of the Association.
10. Inquiries relative to the prize should be addressed to the Secretary.

SCHOLARSHIPS IN AID OF SCIENTIFIC RESEARCH

The Council of the British Medical Association is prepared to receive applications for Research Scholarships as follows: An Ernest Hart Memorial Scholarship of the value of £200 per annum, a Walter Dixon Scholarship of the value of £200 per annum, and four Research Scholarships each of the value of £150 per annum. These scholarships are given to candidates whom the Science Committee of the Association recommends as qualified to undertake research in any subject (including State medicine) relating to the causation, prevention, or treatment of disease. Preference will be given, other things being equal, to members of the medical profession.

Each scholarship is tenable for one year starting on October 1, 1950. The scholar may be reappointed for not more than two additional terms. A scholar is not necessarily required to devote the whole of his or her time to the work of research but may hold an appointment at a university, medical school, or hospital, provided the duties of such an appointment do not interfere with his or her work as a scholar.

Conditions of Award: Applications

Applications for scholarships must be made not later than Friday, April 28, 1950, on the prescribed form to be obtained from the Secretary of the Association, B.M.A. House, Tavistock Square, London, W.C.1. Applicants will be required to furnish the names of three referees who are competent to speak of their capacity for the research contemplated.

CHARLES HILL,
Secretary.

Diary of Central Meetings

NOVEMBER

16	Wed.	**Council**, 10 a.m.
17	Thurs.	Publishing Subcommittee, 11 a.m.
17	Thurs.	Radiologists Group Conference, 1.30 p.m.
17	Thurs.	Radiologists Group Committee (at termination of Group Conference).
23	Wed.	Health Centres Subcommittee of the General Medical Services Committee, 11 a.m.
25	Fri.	Committee on Psychiatry and the Law, 2 p.m.
25	Fri.	Venereologists' Group Committee, 2.30 p.m.

DECEMBER

1	Thurs.	Planning Subcommittee of Occupational Health Committee, 11 a.m.
1	Thurs.	Remuneration Subcommittee of Occupational Health Committee, 2 p.m.
1	Thurs.	Joint Committee of the B.M.A. and the N.V.M.A., 2.30 p.m.
15	Thurs.	Journal Committee, 2 p.m.
22	Thurs.	Occupational Health Committee, 2 p.m.

Branch and Division Meetings to be Held

CAERNARVONSHIRE AND ANGLESEY DIVISION.—At Physics Laboratory Lecture Theatre, St. Deiniol Road, Bangor, Sunday, November 13, 2.30 p.m., sound colour film: "Diagnosis and Treatment, Pathology, and Prognosis of Angina Pectoris."

DUMFRIES AND GALLOWAY DIVISION.—At Oughton's Restaurant, Dumfries, Thursday, November 17, 8.15 p.m. to 1 a.m., dinner-dance.

FURNESS DIVISION.—At Fisherman's Arms, Bardsea, Friday, November 18, 8 p.m., dinner-dance.

GREENWICH AND DEPTFORD DIVISION.—At Miller Hospital, Greenwich High Road, London, S.E., Wednesday, November 16, 8.30 p.m., Dr. Frank Gray: "Rules and Regulations of the N.H.S."

HARROGATE DIVISION.—At Majestic Hotel, Harrogate, Wednesday, November 16, 8.30 p.m., B.M.A. Lecture by Professor L. S. P. Davidson: "The Aetiology and Treatment of Rheumatoid Arthritis with Special Reference to Cortisone (Compound E)."

HERTFORDSHIRE BRANCH.—At Napsbury Hospital, Friday, November 18, 8.30 p.m., clinical meeting. Subject: "Psychiatric Treatment." Films will be shown and a discussion will follow.

KESTEVEN DIVISION.—At Bristol Arms Hotel, Sleaford, Sunday, November 20, 6.30 for 6.45 p.m., dinner; 7.45 p.m., "Some Types of Congenital Heart Disease," by Dr. J. W. Brown.

LEEDS DIVISION.—At Queen's Hotel, City Square, Leeds, Friday, November 18, 8 p.m., dinner and dance.

LEWISHAM DIVISION.—At Lewisham Hospital, High Street, London, S.E., Sunday, November 20, 11 a.m., clinical meeting.

NORTH BEDFORDSHIRE DIVISION.—At Bedford County Hospital, Friday, November 18, 8.30 p.m., clinical evening. Cases to be arranged by Dr. J. L. H. Easton.

NORTH OF ENGLAND BRANCH.—At Royal Victoria Infirmary, Newcastle-upon-Tyne, Thursday, November 17, 7.15 p.m., clinical demonstration by Dr. G. O. Richardson: "Some Clinical Aspects of Diabetes"; 8.45 p.m., address by Dr. J. G. Scadding: "Bronchiectasis."

ROCHESTER, CHATHAM, AND GILLINGHAM DIVISION.—At St. Bartholomew's Hospital, Rochester, Thursday, November 17, 8.30 p.m., clinical meeting. All medical practitioners in the area are invited.

SCARBOROUGH DIVISION.—At Scarborough Hospital, Thursday, November 17, 8.30 p.m. Talk by Dr. J. T. Ingram: "Skin Conditions."

SOUTH MIDDLESEX DIVISION.—At Jersey Rooms, Red Lion Hotel, Hounslow, Thursday, November 17, 8.30 p.m., Dr. Gerald Slot: "Angina and Coronary Thrombosis" (film).

SOUTHAMPTON DIVISION.—At Royal South Hants and Southampton Hospital, Wednesday, November 16, 8.30 p.m., Dr. Robert Forbes: "Legal Hazards of Medical Practice."

STRATFORD DIVISION.—At King George Hospital, Ilford, Tuesday, November 15, 8.45 p.m., clinical meeting. Dr. J. L. Lovibond: "The Clinical Value of Special Diagnostic Tests in the Management of Cardiovascular Disease."

SUNDERLAND DIVISION.—(1) At Royal Infirmary, Sunderland, Thursday, November 17, 3 p.m., annual address by Professor Stanley Davidson: "The Aetiology and Treatment of Rheumatoid Arthritis with Special Reference to the Therapeutic Use of Cortisone (Compound E)." (2) At Seaburn Hotel, Sunderland, November 17, 7.30 p.m., annual dinner.

WEST DENBIGH AND FLINT DIVISION.—At Palace Hotel, Rhyl, Thursday, November 17, 8 p.m., B.M.A. Lecture by Mr. J. W. Tudor Thomas: "Some Observations on Ocular Therapeutics."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY NOVEMBER 19 1949

FURTHER STUDIES CONCERNING THE PARTICIPATION OF THE ADRENAL CORTEX IN THE PATHOGENESIS OF ARTHRITIS

BY

HANS SELYE, M.D., Ph.D., D.Sc., F.R.S.C.

Professor and Director of the Institute of Experimental Medicine and Surgery, Université de Montréal, Montreal, Canada

A few years ago we noted that rats chronically treated with large doses of desoxycortone acetate (D.C.A.) often develop joint lesions which exhibit the histological characteristics of rheumatic arthritis and periarthritis. Curiously, arthritides occurred only in a certain percentage of our experimental animals, although other "rheumatic" changes (e.g., a "rheumatic type" of arteritis, myocarditis, and encephalitis) were constantly present. Furthermore, even when an arthritis developed during the first weeks of treatment it tended to disappear in spite of continued D.C.A. administration; only rarely did such lesions progress towards what might be called an experimental replica of rheumatoid arthritis (Selye, Sylvester, Hall, and Leblond, 1944). In this respect the joint affliction again differed from the other manifestations of D.C.A. overdosage which tend to progress as long as a hormone excess is given.

During subsequent years we occasionally observed an acute joint swelling in D.C.A.-treated monkeys and dogs. Others pointed out that Addisonian patients may develop "rheumatic-like" joint swellings under the influence of D.C.A. overdosage (Dejean, 1947; Dejean, Mahoudeau, and Bricaire, 1947; Laroche, 1947a, 1947b). All these observations revealed that this corticoid exerts a rather specific effect upon joint structures in various species, but the production of arthritis was not constant enough to serve as the basis for systematic studies concerning its pathogenesis.

In the course of experiments planned to increase the incidence of this lesion we noted that, under the influence of D.C.A. overdosage, adrenalectomized rats developed arthritis more frequently than intact controls (Selye, Sylvester, Hall, and Leblond, 1944). This fact was subsequently confirmed on a very large experimental material by my pupil O. Hall (1946). Some actions of mineralocorticoids (such as D.C.A.) are inhibited by gluco-corticoids (such as "cortisone") (Selye, 1949a). Hence it was reasonable to assume that adrenalectomy sensitizes to the toxic effects of D.C.A. because it removes the source of endogenous gluco-corticoids and thereby predisposes to the development of a particularly unfavourable gluco-corticoid/mineralo-corticoid balance.

Several earlier observations had called our attention to the importance of this balance, inasmuch as a mineralocorticoid (D.C.A.) exhibited effects which are diametrically opposed to those of gluco-corticoids. Thus, chronic pretreatment with D.C.A. tends to cause thymus hypertrophy (Selye, 1941; Selye and Beland, 1943), while gluco-corticoids exert an opposite effect (Selye, 1946). D.C.A.-pretreated rats respond to various stress-producing agents (cold, formaldehyde injections, atropine injections, surgical trauma, exercise) with hypoglycaemia instead of the usual hyperglycaemia characteristic of the alarm reaction (Selye and Dosne, 1942); conversely, adreno-cortical extracts (rich in gluco-corticoids) increase the hyperglycaemic response to stress even in the adrenalectomized animal (Selye and Dosne, 1941). The development of shock after surgical trauma is aggravated by D.C.A. pretreatment and mitigated by corticosterone (a gluco-corticoid compound) (Selye, Dosne, Bassett, and Whittaker, 1940). It has been noted, furthermore, that the hypertension which can be elicited in sensitive patients by D.C.A. overdosage is abolished by an adrenal extract rich in gluco-corticoids (Perera and Pines, 1949).

On the basis of these and many other observations we came to the conclusion that D.C.A., when it is given in toxic concentrations, may create a "partial hypocorticoidism"; in other words, it can cause a condition in which manifestations of hypo- (decreased resistance to stress, thymus enlargement, hypoglycaemia) and hypercorticoidism (sodium retention, hypertensive disease) are simultaneously manifest. It is also noteworthy in this connexion that, although the clinical condition of Addisonian patients is improved by moderate doses of D.C.A., they are hypersensitive to the toxic effects of this steroid—presumably again because these individuals are deprived of the antagonistic gluco-corticoids (Selye, 1949a).

Quite recently Pirozynski and Akert (1949) noted that, even when no macroscopically visible arthritis develops in D.C.A.-treated rats, one consistently finds histological evidence of a "rheumatic-like" joint involvement. These authors confirmed that adrenalectomy sensitizes the rat to the production of joint lesions by D.C.A. They discovered, furthermore, that even the extra-articular manifestations of D.C.A. overdosage (such as cardiovascular and renal lesions) are aggravated by adrenalectomy, probably because the source of the protective gluco-corticoid had been removed.

Subsequently it was found that "rheumatic" changes in the heart and joints, similar to those produced by D.C.A., can also be elicited by a crude lyophilized anterior pituitary (L.A.P.) preparation, but only in the presence of the adrenals. Since adrenalectomy prevented these effects of L.A.P., it was concluded that they are largely, if not entirely, mediated through the adrenal cortex, perhaps owing to the discharge of some D.C.A.-like mineralocorticoid compounds (Selye, 1946).

In the course of our work on the general-adaptation syndrome, it became obvious that in response to a variety

obtained from the Secretary. Essays must be forwarded to reach the Secretary, British Medical Association, B.M.A. House, Tavistock Square, London, W.C.1, not later than March 31, 1950. The prize will be awarded at the Annual Meeting of the Association to be held in 1950. Inquiries relative to the prize should be addressed to the Secretary.

SIR CHARLES HASTINGS CLINICAL PRIZE

The Sir Charles Hastings Clinical Prize, which consists of a certificate and a money award of 50 guineas, is again open for competition. The following are the regulations governing the award:

1. The prize is established by the Council of the British Medical Association for the promotion of systematic observation, research, and record in general practice.
2. Any member of the Association who is engaged in general practice is eligible to compete for the prize.
3. The work submitted must include personal observations and experiences collected by the candidate in general practice, and a high order of excellence will be required. If no essay entered is of sufficient merit no award will be made. It is to be noted that candidates in their entries should confine their attention to their own observations in practice rather than to comments on previously published work on the subject, though reference to current literature should not be omitted when it bears directly on their results, their interpretations, and their conclusions.
4. Essays, [illegible] essays, must be [illegible] to us at [illegible]

Branch and Divisi[illegible] were readily available

[illegible] formation of mineralo-corticoids is postulated almost entirely on the basis of indirect evidence, because of the great technical difficulties involved in the determination of these latter compounds. It should be kept in mind, however, that even if the absolute amounts of mineralo-corticoids were not increased their effect could be augmented owing to sensitization (e.g., by sodium retention or renal failure), or the gluco-corticoid/mineralo-corticoid quotient may become unfavourable.

At the time of our first observations the assumption of a pathogenetic relationship between the adrenal cortex and the "rheumatic-rheumatoid type" of arthritis appeared rather far-fetched. However, this view received strong support from recent clinical observations. It was noted that adrenal-cortical extracts (Bassi and Bassi, 1946), which are notoriously rich in gluco-corticoids, and especially cortisone (Hench, Kendall, Slocum, and Polley, 1949), a typical gluco-corticoid compound, produce spectacularly beneficial effects in patients with chronic rheumatoid arthritis. It is of special interest in this connexion that purified adrenocorticotrophic hormone (A.C.T.H.) is also effective in rheumatoid arthritis (Hench, Kendall, Slocum, and Polley, 1949), since normally this compound appears to stimulate particularly the production of gluco-corticoids.

On a purely empirical basis, so-called non-specific therapeutic procedures (e.g., parenteral injection of foreign proteins or colloidal metals, blood-letting) have long been used in the therapy of rheumatoid arthritis. It is presumably due to the same mechanism that this joint lesion can improve under the influence of a variety of other non-specific stress-producing conditions, such as pregnancy, icterus, traumatic injuries, and starvation (Hench, 1949). All these are highly effective "alarming stimuli"—that is, they can produce a condition of systemic stress with the characteristic endogenous discharge of pituitary A.C.T.H. (Selye, 1946, 1949a; in the press). As we have said elsewhere, probably the most important factor in the therapeutic action of "non-specific therapy," "fever therapy," and "shock therapy" is the fact that such drastic measures stimulate defence by eliciting a general-adaptation syndrome, and, more particularly, an increased production of A.C.T.H. (Selye, 1949b; in the press). The observation that potent gluco-corticoid and A.C.T.H. preparations are especially effective in combating rheumatoid arthritis agrees with this view.

It remains to be seen why certain impure anterior pituitary preparations (e.g., L.A.P.) often produce arthritis

Recently we succeeded in developing a simple technique for the consistent production of arthritic and periarthritic changes, and, having now obtained adequate amounts of the anti-arthritic hormone preparations (A.C.T.H. and cortisone), we were able to analyse further the role of the pituitary adreno-cortical system in the production and prevention of arthritis. It is upon this work that we report in the present communication.

Methods

The *experimental animals* used in this study were adult male Wistar albino or piebald rats. The *experimental arthritis* was produced by the injection of dilute formaldehyde solutions of varying concentration (see description of individual experiments) just beneath the plantar aponeurosis of the hind paws. Normally, this strong irritant produces an intense hyperaemia and oedema of the entire paw within a few minutes.

As we shall see below, the action is increased by pretreatment with D.C.A. or L.A.P. and diminished by previous administration of A.C.T.H. or cortisone. We had noted in earlier experiments that the effect of various hormones largely depends upon the sensitization or desensitization of the target organs by peripherally acting "conditioning factors." Thus, the production of nephrosclerosis or arteriosclerosis by D.C.A. depends upon the sodium content of the diet (Selye, 1949a). In the present instance, however, formaldehyde as an irritant is the actual eliciting factor, while the hormone preparations appear to act as "conditioning factors" determining the degree of response.

About 10 days after the first hyperaemic and oedematous response vanishes, a secondary more chronic type of joint reaction becomes manifest. By this time most of the oedema has subsided, but the surrounding skin remains intensely hyperaemic and the periarticular connective tissue begins to proliferate, especially in the ankle-joint region. It is somewhat unexpected that the injection of the irritant at some distance from the ankle-joint should produce a secondary response in this articulation, but numerous observations leave no doubt concerning the selective responsiveness of the ankle-joint region during the chronic indurative stage. Probably the stretching of tissues incident to the great mobility of this joint is responsible for this.

In the course of our preliminary experiments we compared the inflammatory response to a given quantity of formaldehyde in various organs—for instance, the

FURTHER STUDIES CONCERNING THE PARTICIPATION OF THE ADRENAL CORTEX IN THE PATHOGENESIS OF ARTHRITIS

BY

HANS SELYE, M.D., Ph.D., D.Sc., F.R.S.C.

Professor and Director of the Institute of Experimental Medicine and Surgery, Université de Montréal, Montreal, Canada

frequently it continues [illegible] noted that rats chronically treated with discontinued, so that eventually [illegible]state (D.C.A.) often develop mously enlarged, stiff, and extremely painful to touch. We shall report upon the histogenesis of this lesion elsewhere; suffice it to say here that, microscopically, in the acute oedematous stage it resembled the rheumatic, in the chronic stage the rheumatoid, type of arthritis. For the sake of simplicity we shall merely refer to these changes as the acute and chronic phases of "formalin-arthritis" (see Fig. 1).

Corticotrophin (*A.C.T.H.*) was administered subcutaneously in the form of a solution containing 5 mg. per ml. of physiological saline. Two highly purified preparations were supplied by the Armour Company, of Chicago: "lot 60–61," which has a biological potency of 100% Armour Standard La-I-A, contains 0.03 unit of oxytocin and 0.06 unit of vasopressin per mg.; "lot 64–A" has a biological potency of 180% of Armour Standard La-I-A and contains 0.03 unit of oxytocin per mg. Both these preparations are contaminated by only negligible amounts of the remaining known pituitary factors.

FIG. 1.—On the left, hind paw of a normal rat; on the right, hind paw of a rat which received three injections of a 1% formaldehyde solution under the palmar aponeurosis at two-day intervals one month before this picture was taken. Note the typical appearance of the chronic "formalin arthritis." The lesion is largely limited to the ankle-joint, which became almost immobilized by the hard cartilage-like indurating granulomatous vegetation. The skin covering this region is very hyperaemic and the joint extremely tender to touch.

Lyophilized anterior pituitary (L.A.P.) was injected subcutaneously in the form of a preparation containing 40 mg. of lyophilized cattle anterior pituitary powder, suspended in a 10% aqueous alcoholic solution.

Cortisone was given subcutaneously as a saline suspension of cortisone acetate microcrystals, each millilitre containing 25 mg. The preparation was that distributed by Merck and Co., Rahway, N.J., in which suspending agents (to keep the microcrystals from settling) and 1.5% benzyl alcohol (as a preservative) are added.

formaldehyde injections, atropine injections, surgical trauma, exercise) with hypoglycaemia instead of the usual in the form of a microcrystalline suspension. [illegible] days later all animals of both groups were injected with 0.1 ml. of a 4% formaldehyde solution into the right hind paw, as described above. A second similar injection was given into the same paw four days later. Immediately after each injection the initial hyperaemic and oedematous response to the local irritation was approximately the same in both groups. However, a few days after each injection the oedema tended to subside much more in the untreated than in the D.C.A.-injected rats. The experiment was terminated on the 14th day after the first formaldehyde injection, at which time the oedema, induration, and hyperaemia of the paw were significantly more pronounced in the D. C. A. - pretreated than in the control rats (see Fig. 2). It must be emphasized, however, that the high concentration of formaldehyde used in this first experiment caused actual necrosis in the plantar skin, and hence the inflammatory response was quite intense and diffuse (not limited to the ankle region) even in the controls. In spite of this intense local damage, D.C.A. pretreatment aggravated the inflammatory response.

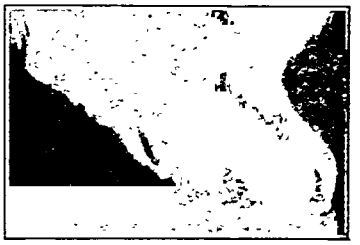

FIG. 2.—Hind paw of a rat pretreated with D.C.A. (left) and a not pretreated rat. Both animals were injected with the same amount of formaldehyde into the joint region, yet the D.C.A.-treated animal developed a much more pronounced inflammatory reaction.

Effect of D.C.A. and Cortisone upon the Subacute and Acute Stage of "Formalin Arthritis"

The second experiment was designed to examine the effect of D.C.A. and cortisone (both in themselves and in combination with each other) on the development of "formalin arthritis." For this purpose we used 40 male piebald rats weighing 120–150 g. All animals were bilaterally adrenalectomized on the first day of the experiment in order to eliminate any complicating endogenous corticoid formation. They were then subdivided into four groups of ten rats each: group I, no hormone treatment; group II, D.C.A.; group III, D.C.A. and cortisone; group IV, cortisone. D.C.A. was administered in the form of two 25-mg. pellets subcutaneously on the day of the

adrenalectomy. Cortisone was given in two 2.5 mg. injections daily subcutaneously. All animals received 1% NaCl as drinking fluid in order to help their survival after adrenalectomy and also because a sodium supplement aggravates D.C.A. intoxication.

An injection of 0.1 ml. of a 1% formaldehyde solution was given in the usual manner into the right hind paw on the second and fourth days after adrenalectomy. On the fifth day the swelling was very mild in the groups receiving cortisone or cortisone and D.C.A., while it was pronounced in the remaining two groups. There was no clear-cut difference between groups I and II (no hormone treatment or D.C.A. alone) nor between those of groups III and IV (cortisone alone or in combination with D.C.A.). At this time another injection of 0.1 ml. of a 2% formaldehyde solution was administered into the left hind paw, with the remarkable result that even three hours after the injection of this rather concentrated solution none of the two cortisone-treated animals (groups III and IV) responded, while the untreated animals, and especially those bearing the D.C.A. pellets, developed a marked hyperaemia and oedema, especially in the ankle region (see Fig. 3).

FIG. 3.—Cortisone-pretreated (left) and D.C.A.-pretreated adrenalectomized rats. Both animals received the same amount of formaldehyde, yet the cortisone-pretreated rat failed to respond, while the animal receiving D.C.A. developed a very pronounced and persistent inflammatory reaction. Adrenalectomized rats of this group receiving both cortisone and D.C.A. also failed to respond, while not pretreated adrenalectomized controls reacted violently, though not quite as much as those receiving D.C.A.

II. Experiments with Hypophyseal Preparations

Effect of A.C.T.H. upon the Acute Stage of "Formalin Arthritis"

Having learned that both in more chronic and in acute experiments cortisone inhibits, while D.C.A. tends to aggravate, "formalin arthritis," it appeared of interest to determine whether A.C.T.H. would act like cortisone, since in so many other respects these two hormones have similar properties. Twelve male Wistar albino rats weighing 120–180 g. were subdivided into two groups of six animals each. Group I received no hormone treatment, while in group II each animal was given 2.5 mg. of A.C.T.H. ("lot 60–61") subcutaneously. Twenty-five minutes later all animals of both groups received 0.1 ml. of a 1% formaldehyde solution into the left hind paw in the usual manner. Again the controls showed an almost immediate hyperaemic and oedematous response at the site of injection, while the A.C.T.H. pretreated animals exhibited only a very slight hyperaemia with almost no oedema. Two hours after the first injection an additional 2 mg. of A.C.T.H. was administered in group II. It was noted that in these animals the local response to the formaldehyde, though detectable, was extremely mild, even several hours after the second A.C.T.H. injection; by this time the paws of the control animals were very hyperaemic and so intensely swollen that the skin covering the plantar surface became shiny from extreme distension (see Fig. 4).

FIG. 4.—A.C.T.H.-treated (left) and not pretreated control. Both animals received the same amount of formaldehyde, yet the A.C.T.H.-treated animal almost completely failed to respond, while the control developed a pronounced oedema of the periarticular tissue and a pronounced hyperaemia of the skin almost immediately after the formaldehyde injection. Unlike the intact control, the A.C.T.H.-pretreated rats of this group gave no particular manifestations of pain when the joint region was touched.

Effect of A.C.T.H. upon the Chronic Stage of "Formalin Arthritis"

Having thus established that the acute local response to formaldehyde is inhibited by an immediately preceding injection of A.C.T.H., we undertook another experiment to examine the influence of prolonged A.C.T.H. treatment upon chronic "formalin-arthritis." Twelve male piebald rats weighing 120–136 g. were subdivided into two groups of six. Group I acted as controls, group II received 5 mg. of A.C.T.H. (lot 64-A) daily subcutaneously, subdivided into five injections of 1 mg. each. After two weeks of this pretreatment the animals of both groups received 0.1 ml. of a 4% formaldehyde solution administered into the right hind paw in the usual manner. With this dosage the immediate oedematous reaction was almost the same in the A.C.T.H.-treated and in the control animals, but in the former the swelling subsided rapidly while in the latter it persisted for several days. Seven and again 12 days later 0.1 ml. of a 1% formaldehyde solution was injected into the same paw in all animals.

After each injection the immediate response was almost as pronounced in the A.C.T.H.-pretreated as in the control animals, but, while in the former only a trace of oedema persisted a few days after each

FIG. 5.—A.C.T.H.-pretreated (left) and not pretreated control. After a few A.C.T.H. injections both these animals were given repeated injections of the same amount of formaldehyde into the paw. The controls developed marked indurative chronic arthritic and periarthritic lesions; the A.C.T.H.-pretreated animals showed only a negligible response.

FIG. 6.—Plantar view of the specimens shown in Fig. 4. Note that although the direct necrosis-producing effect of the formaldehyde injection was the same in both cases, the A.C.T.H.-pretreatment (left) almost completely prevented the proliferative inflammatory response to the local tissue injury which is so evident in the control.

injection and no cumulative effect was detectable, in the latter the inflammation became increasingly more pronounced and gradually proceeded towards induration. By the 25th day after the first A.C.T.H. injection all the control animals had developed a pronounced and proliferative indurating inflammatory lesion, especially in the ankle-joint region, but to some extent also around the metatarsal joints. In several of the A.C.T.H.-treated rats there was also a barely detectable oedema of the paw, but without predilection for the ankle-joint region and without induration. In this series, where the first injection consisted of the concentrated (4%) formaldehyde, definite necrotic changes were obvious in the plantar region of all animals in both groups. This necrosis presumably resulted from the protein-precipitating (fixative) action of the formaldehyde, which of course could not be inhibited by the hormone treatment. It is especially instructive to note that in spite of the creation of an equally severe necrotic focus the inflammatory response to the irritation was so effectively suppressed by the hormone treatment (see Figs. 5 and 6).

Comparative Study of the Effect of L.A.P. and A.C.T.H. upon "Formalin Arthritis"

It will be recalled that in our earlier experiments L.A.P. occasionally produced arthritis even without any local trauma to the joints, while in the above-mentioned groups A.C.T.H. inhibited the development of "formalin-arthritis"; hence we wanted to compare the effect of the two hormone preparations under similar experimental conditions. For this purpose 18 male piebald rats weighing 120–150 g. were subdivided into three groups of six animals each. Group I received no hormone preparation; group II were given 40 mg. of L.A.P. daily, divided into five doses; and group III received 10 mg. of A.C.T.H. (lot 60-61) daily, divided into five doses. On the first, second, and third day of the experiment the rats of all groups were given 0.1 ml. of a 1% formaldehyde solution into the right hind paw in the usual manner. Here again the immediate response to the irritant was only slightly less pronounced in the A.C.T.H.-pretreated than in the other two groups. However, about 24 hours after each injection the oedema had subsided most markedly in the A.C.T.H.-treated animals and remained especially pronounced in those receiving L.A.P. This difference became quite obvious two days after the last formaldehyde injection. Thus A.C.T.H. greatly diminished, while L.A.P. slightly increased, the arthritis-producing effect of formaldehyde.

Our earlier observations had revealed that A.C.T.H. (like cortisone) causes rapid involution of the thymus and other lymphatic organs. This response is also manifest during the alarm reaction produced by any agent capable of causing systemic stress effects (e.g., nervous stimuli, infections, intoxications, exposure to cold), while L.A.P. tends to enlarge the thymus and the lymph nodes (Selye, in the press). It had been observed, furthermore, that during the alarm reaction the phagocytic power of the macrophages is considerably augmented, presumably due to increased A.C.T.H. and gluco-corticoid hormone production (Selye and Timiras, in the press). Since phagocytosis plays an important part in inflammatory reactions we added a few drops of commercial indian ink (Higgins's "American India ink") to the formaldehyde used in this experiment for the production of arthritis. This made it possible simultaneously to follow the process of phagocytosis. Upon necropsy of the rats on the second day after the last formaldehyde injection it became immediately obvious that, on the formalin and indian ink injected side, the popliteal and iliac lymph nodes were most markedly stained in the A.C.T.H. group and least markedly in the L.A.P.-treated animals. The size of these lymph nodes, on the other hand, was smallest in the A.C.T.H.-treated and largest in the L.A.P.-treated rats. Thus, apparently, the removal of the indian-ink particles was accelerated by the A.C.T.H. and inhibited by the L.A.P. preparation, while the morphologic

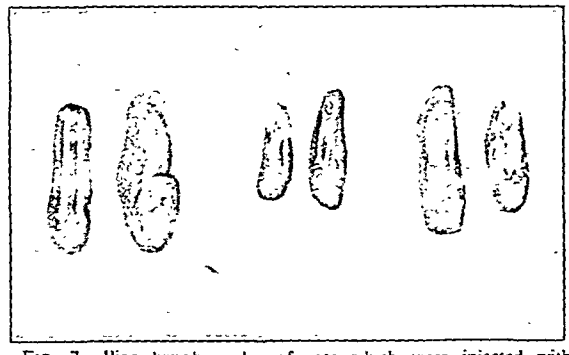

FIG. 7.—Iliac lymph nodes of rats which were injected with formaldehyde and indian ink into the joint region. On the left, not hormone treated control; in the middle, A.C.T.H.; on the right, L.A.P. pretreated animals. Note the A.C.T.H. increases phagocytosis but diminishes the size of the lymph nodes, while L.A.P. exerts contrary effects.

development of the lymph nodes was promoted by L.A.P. and diminished by A.C.T.H. (see Fig. 7). At the same time we confirmed that A.C.T.H. causes pronounced thymus involution while L.A.P. tends to augment the development of the thymus. This latter finding is all the more remarkable since the adrenal cortical enlargement produced by A.C.T.H. and L.A.P. was almost exactly the same at the dose level employed in this experiment. The adrenals of the untreated controls weighed 21±1 mg., those of the A.C.T.H.-treated rats 30±3 mg., and those of the animals receiving L.A.P., 32±2 mg. This would imply that at the dose level used the corticotrophic effect of the two preparations was quite comparable in degree, as judged by the ability of these preparations to cause adreno-cortical hypertrophy, yet the thymolytic and lympholytic effect was manifest only with pure A.C.T.H. Perhaps some contaminating substances present in the L.A.P. but absent in the A.C.T.H. counteract certain manifestations of the pure corticotrophic hormone.

Effect of the Alarm Reaction Upon the Development of Formaldehyde Arthritis

The last experiment of this series was planned to examine the effect of an alarm reaction (produced by various means) upon the response of the joint tissues to local formaldehyde injection.

Fifty male piebald rats weighing 150–200 g. were subdivided into five groups of ten animals each. Group I served as not pretreated controls. In group II an alarm reaction was produced by forced exercise in a drum cage 12 in. (30 cm.) in diameter and revolving at a speed of 12 revolutions per minute. The animals were forced to run three to four hours at a time, the revolving cage being stopped for a few hours whenever one or two animals of the group were too tired to run. Group III were exposed to a temperature of +1 to +3° C. during 24 hours. In group IV stress was produced by transection of the spinal cord at the level of the seventh cervical vertebra. In group V 0.5 ml. of a 10% formaldehyde solution was injected subcutaneously in the region between the shoulder blades four times during 24 hours. Since fasting increases the ability of various damaging agents to cause an alarm

reaction, all animals of groups II to V inclusive were fasted 24 hours before, as well as during the exposure period. Since all stresses were applied during 24 hours, the total period of fasting was 48 hours. At the end of this time 0.1. ml. of a 2% formaldehyde injection was injected in the usual manner into the right hind paw. Fifteen minutes later pronounced hyperaemia and oedema had developed in the not pretreated control animals of group I while none of the alarmed animals showed more than a trace of hyperaemia or oedema; most of them did not react at all.

It should be specially emphasized that, although some of the alarmed animals were in a very debilitated condition, those which showed no obvious signs of weakness likewise failed to respond to formaldehyde. Hence the failure to react cannot be ascribed merely to a decreased vitality.

FIG. 8.—On the left, untreated control. Note normal appearance of the hind paw. In the middle, unpretreated control showing pronounced oedema and hyperaemia of the paw after local formaldehyde injection. On the right, paw of an animal in which an alarm reaction was produced by spinal-cord transection. Note almost complete absence of hyperaemia and oedema. The paw is practically indistinguishable from the intact control, although the same amount of formaldehyde was injected into it. A variety of other alarming stimuli (cf. text) exerted the same inhibitory effect.

This view receives further support from our previously mentioned observations on adrenalectomized animals. Many among these were almost moribund at the time of formaldehyde injection and yet responded with pronounced periarticular swelling. We are inclined to assume, therefore, that in this experiment endogenous secretion of A.C.T.H., and consequently of gluco-corticoids, was responsible for the inhibition of the "formalin-arthritis" (see Fig. 8).

Discussion

If we now attempt to evaluate these observations the concept of "non-specific resistance" or "crossed resistance" first comes to mind. We had repeatedly observed that during an alarm reaction, produced by diverse means, both the specific and the non-specific resistance of the organism rise above normal. That is, the exposed individual becomes more resistant not only to the particular damaging agent with which the alarm reaction was elicited but also to entirely unrelated stimuli. Thus an alarm reaction produced by cold, forced muscular exercise, spinal-cord transection, etc., increases resistance against the fatal lung oedema produced by toxic doses of adrenaline, anaphylactic and anaphylactoid reactions, etc. Since such manifestations of crossed resistance were invariably accompanied by histological signs of increased adreno-cortical activity, and since they were never observed in adrenalectomized animals exposed to stress, they had tentatively been ascribed to an increased production of corticoids during the alarm reaction (Selye, 1946; in the press).

We have reported elsewhere upon experiments showing that in the rat anaphylactoid reactions to egg-white can also be effectively inhibited by A.C.T.H. and cortisone (Selye, 1949c).

It is rather probable that in the final analysis the inhibition of "formalin-arthritis" by A.C.T.H., cortisone, and the alarm reaction is due to the effect of cortisone-like glucocorticoids upon the directly injured tissues. The mechanism of this response is still unknown. It may be related to the anti-hyaluronidase effect of gluco-corticoids (Seifter, Baeder, and Dervinis, in the press), or to their well-known antihistaminic action. It has long been assumed that histamine-like compounds are liberated from tissues at the site of injury, and that these play an important part in inflammation. It is noteworthy, therefore, that the phenomena of "crossed resistance" which can most effectively be compared by the alarm reaction are also markedly inhibited by antihistaminic drugs (e.g., lung oedema, anaphylactic and anaphylactoid reactions). In view of this observation it would be interesting to examine the value of antihistaminics in some of the clinical conditions (e.g., rheumatic fever, rheumatoid arthritis, and lupus erythematosus) which have been effectively combated with cortisone or A.C.T.H.

It is particularly difficult to explain the apparent antagonism between D.C.A. or L.A.P. on the one hand and cortisone or A.C.T.H. on the other. Perhaps D.C.A., being a close chemical relative of cortisone, prevents the latter from reaching its target organs; this might be due to some mechanism of "competition for the substrate," such as has been demonstrated to exist between adrenaline and certain adrenaline derivatives, or vitamins and their corresponding anti-vitamins. However, this possibility is meanwhile purely hypothetical.

It is curious that the impure pituitary preparation L.A.P acts like D.C.A., while purified A.C.T.H. exerts cortisone-like effects. L.A.P. contains A.C.T.H., and under the conditions of our experiments it produced an equally pronounced adrenal cortical enlargement; hence we must consider the possibility that the pituitary contains additional principles which antagonize the A.C.T.H. effect or so modify it that a D.C.A.-like action results. This may be important in the pathogenesis of the "diseases of adaptation." It will be recalled that under certain conditions chronic exposure to stress (e.g., cold, parenteral protein administration) causes nephrosclerosis, myocarditis, hypertension, and arteriosclerotic changes similar to those produced by D.C.A. or L.A.P. (Selye, 1946; in the press).

Finally, it must be kept in mind that the "anti-arthritic effect" of A.C.T.H. and cortisone is by no means specifically directed against the hypothetical pathogen which causes rheumatoid or rheumatic joint lesions. Clinical observations have shown A.C.T.H. to be highly effective also in gouty arthritis (Thorn, Bayles, Massell, Forsham, Hill, Smith, and Warren, 1949), and our observations reveal that even the arthritis caused by formaldehyde—an obviously entirely non-specific inflammatory reaction—is effectively prevented by A.C.T.H. and cortisone. It should be mentioned that upon discontinuation of A.C.T.H. treatment in patients predisposed to gout an attack of arthritis can be elicited (Hellman, 1949; Thorn, *et al.*, 1949). Correspondingly, in many of our experiments (not reported here) we noted that if a "formalin-arthritis" is inhibited by an

alarming stimulus during a period of one to two days it usually flares up in a particularly severe form upon discontinuation of the stress—e.g., cold, muscular exercise. Indeed, sometimes the arthritis developed after a latency period even if the stress was continued. Such observations raise the question whether it will be possible to combat clinical "diseases of adaptation" indefinitely by continued A.C.T.H. or cortisone therapy.

Summary and Conclusions

A technique has been developed which permits the production of an acute arthritis and periarthritis by the local injection of formaldehyde into the vicinity of joints. If large doses of formaldehyde are administered the acute stage is followed by a very prolonged chronic arthritis and periarthritis, characterized by moderate oedema and very pronounced connective-tissue proliferation, with stiffening of the joint and hyperaemia of the surrounding skin. The resulting chronic granuloma is self-maintaining, as it continues to proliferate for weeks after the administration of the local irritant.

This "formalin-arthritis" is slightly aggravated by pretreatment with desoxycortone or crude anterior-pituitary preparations; on the other hand it can be almost completely inhibited by cortisone or A.C.T.H. Thus there seems to exist an antagonistic relationship between D.C.A. or crude anterior-pituitary preparations on the one hand and cortisone or purified A.C.T.H. on the other.

The possible role of such an antagonism is discussed in connexion with the concept of "crossed resistance" and of the "diseases of adaptation."

This investigation was performed with the aid of a grant from the Canadian National Research Council. I am also indebted to the following companies, who supplied the hormone preparations necessary for this work: Merck and Co., Rahway, N.J. (cortisone acetate); Armour and Company, Chicago (A.C.T.H.); Schering Corporation, Bloomfield, N.J. (desoxycortone acetate); and F. W. Horner and Co. (lyophilized anterior-pituitary tissue). Special thanks are due to Mr. Kai Nielsen for the photographs and to Mr. Bernard Messier for technical aid.

TUBERCULOSIS IN EUROPE DURING AND AFTER THE SECOND WORLD WAR

BY

MARC DANIELS, M.R.C.P., D.P.H.

Member of the Scientific Staff of the Medical Research Council

THE TUBERCULOSIS SERVICES*

Before describing the reorganization of the tuberculosis services in the different European countries it may be helpful to say something of the conditions Unrra found in some of these countries at the end of the war. A preliminary stage of the Unrra programme was to study these conditions at close quarters, assess the damage, and make proposals for a programme of relief and rehabilitation on the basis of this assessment. Travelling throughout the countries as we did, discussing problems with people of all kinds, we were in a position often to get an exceptional overall view of the situation, and were in fact able to report back to the central authorities much that was unknown to them. It is only by remembering what these conditions were that we can appreciate what has been achieved since then.

It is difficult in this country to realize the extent of the disruption and destruction in some of the countries. Of those we saw, none had suffered more than Poland. The occupation had been brutal against a continuous opposition—the avowed German policy had been one of systematic reduction of the Poles to the status of a slave people, and a part of this policy had been the killing of professional and skilled workers. Some six million people of the total population of 33 millions had been killed in concentration camps, at their work, in their homes, or elsewhere. All higher education was stopped. The city of Warsaw was systematically destroyed till less than 10% of buildings were left standing, and other cities were similarly destroyed. The tragic war years were reflected in all we saw: when we went in we found towns that had throughout their area the look of some patches we know around St. Paul's or in the East End. Vast areas of farmland had been laid waste. People were living in cellars, dug-outs, in shells of buildings—one, two, or three families together in a room. Nearly all had lost relations in concentration camps or had spent years in camps themselves; there were half a million orphans; thousands of people were migrating from one area to another; thousands were returning from other countries. In the midst of all this the Polish people were attempting to rebuild—to provide homes, food, and services.

Dr. Gould, who visited Yugoslavia for Unrra, tells a similar story. In his words: "All the factors which tend to increase the incidence and mortality of tuberculosis became particularly acute during the war years. Entire villages had been burned after being plundered of food, clothing, livestock, and valuables. Men and women had been deported as slave labourers. With the combination of enemy action and civil strife the public health service was completely disorganized. Trained tuberculosis doctors and nurses were dispersed and lost."

Dr. McDougall reported from Greece: "In spring, 1945, when Unrra was invited to make a survey of tuberculosis requirements in Greece, after four years of German, Italian, and Bulgarian occupation and a month or more of civil

*The second Milroy Lecture (abridged) delivered at the Royal College of Physicians on February 17. The first lecture appeared last week.

war, it was clear that public health organization was completely out of hand. . . . During the occupation malnutrition had assumed epidemic proportions; anaemia and emaciation were the common lot of the majority of the population." But later he observes that after the war the great problem was not shortage of food but its cost, resulting from the lack of control of prices, black-marketeering, and the sale of imported food supplies by the Government at exorbitant rates.

It is against this background of countries physically and sometimes morally maimed that one must consider the tuberculosis services in the post-war period. The increase in mortality and the high incidence revealed by *x*-ray surveys set the first priority—the finding of hospital beds for the tuberculous sick.

Hospitals and Sanatoria

In Poland during the war all sanatoria had been occupied by the Germans. When they left they took instruments and equipment; buildings were left in a sorry condition. Even before the war there were only 8,300 beds for the tuberculous, representing about one bed per six deaths from tuberculosis. At the end of the war only 800 beds were available; but by May, 1946, there were already some 5,000 beds occupied. Buildings had been restored and supplied with Unrra beds, bedding, and equipment: this represented not only the large contributions by Unrra, but an effective and honest distribution by the Poles themselves, despite the occasional chaos in administration because experienced people were so few. By the end of 1947 there were over 11,500 beds for tuberculosis in sanatoria and hospitals; now they have 17,000—i.e., twice as many as before the war, and for a smaller population.

A major problem was the financing of hospital and sanatorium treatment. Before the war it was paid for by the Social Insurance Organization, the Red Cross, the local authorities, or the individual patient. Those dependent on their local authorities were the least likely to get treatment for an adequate time, if at all. Some of the best sanatoria were owned, directed, and staffed by the Social Insurance Organization. After the war this situation was unchanged, and there was in fact little co-ordination between insurance, private, and public sanatoria. The money provided from public funds was so meagre that, though there were too few beds for the tuberculous, some were empty because there were no funds to pay for patients in them. However, the State contributions to sanatorium treatment have increased considerably each year, and that problem has been resolved. Moreover, since the beginning of this year the split in the services between the Social Insurance Organization and the Ministry of Health no longer exists; the hospitals are now directed by the Ministry of Health, while the Social Insurance Organization has the function of financing the treatment of insured persons.

The conflict between social insurance organizations and the central health services was one we saw reproduced, with much more startling anomalies, in other countries, particularly in Italy. There before the war the National Insurance Organization (I.N.P.S.) had built what were the finest sanatoria in the country. There were few reputable sanatoria belonging to any other organization. Few of the sanatoria were damaged during the war, and in fact in 1945 the situation was very much as before, though some hundreds of beds were still controlled by the military authorities. Insured patients could be admitted to sanatoria of the I.N.P.S. as soon as diagnosed, regardless of their condition, whereas for the very large numbers of non-insured patients (some 60% of the population) there was in many areas little hope of getting hospital treatment at all. Beds in I.N.P.S. sanatoria could be rented by the local authorities, but only when these could pay. In one typical poor district visited no taxes were being paid, and for lack of funds the local authorities with a waiting-list of 240 patients had not been able to send a single patient to hospital for four months, while the Insurance Sanatorium, on the outskirts of the town, had 70 empty beds.

Another outstanding problem in countries where there was a shortage of hospitals was the type of accommodation required for the tuberculous. One striking feature of the sanatoria in Italy apart from their excellent equipment was their size. The Forlanini Institute had 2,000 beds. Another sanatorium, completed in 1939 at Sondalo, in the Italian Alps, was designed to accommodate 3,000 patients. Described as a sanatorium village, it consisted of nine large buildings grouped closely together on the side of a steep mountain. Though the medical treatment in some of the large sanatoria was of a high quality, the dangers inherent in their size were not averted; the lack of a personal element in supervising the welfare of patients was obvious.

In most other countries it has been interesting to observe a definite swing away from the conception of sanatoria as large luxurious establishments up in the mountains. In Holland, where three sanatoria were destroyed in the course of the fighting, it was decided to erect wooden hutment buildings in connexion with existing institutions. It was planned to do this on an extensive scale, and, though the scheme was held up by shortage of material and fittings, several temporary sanatoria were set up, yielding a total of over 1,100 new beds for the tuberculous. In Hungary before the war there were some 6,500 tuberculosis beds; in the spring of 1945 only about 500 beds were available. By 1948 many of the hospitals had been restored, and over 5,000 beds were in use for tuberculous patients. But at least another 8,000 are required, and the present plans are to set up hutment buildings of the Swedish type around existing hospitals, providing treatment, nursing, and food from the central building. Later on the huts not needed might serve for recreation and workshops. In Poland the Swedish Red Cross set up not far from Warsaw a whole children's sanatorium made of excellent hutment wards, with well-equipped and cheerful interiors. In Greece, where there was a dire overall shortage of accommodation, Dr. McDougall elaborated a programme for the supply of prefabricated buildings which would accommodate an additional 5,000 beds and 30 polyclinics; the scheme received enthusiastic support from the Ministry of Health under one Government, but there were many interests involved, and under another Government the scheme was dropped.

In several countries, in addition to erection of these pavilions, other buildings were being taken over, such as country villas, hotels, castles, and spa buildings, and were being converted for use as small tuberculosis hospitals. It is mainly by such means that in Yugoslavia, for instance, the number of tuberculosis beds has been increased from the pre-war figure of 3,250 to 10,300 in 1949. Some countries have decided that 5–10% of the beds in general hospitals in the towns must be assigned, at least provisionally, to the care of tuberculous patients; given adequate precautions against contagion, this is a measure which might well be given serious consideration in our own country (Boland, 1948).

Related to standards in England, the level of hospital care in some of these countries, and particularly in some areas, was low. Special post-war conditions aggravated the situation. It was not rare to find hospitals where

patients had to bring their own linen if they were to have any, and no drugs were provided; frantic relatives would spend much time trying to buy such drugs as calcium gluconate on the black market, to say nothing of penicillin and, later, streptomycin. To speak of these conditions is not to imply that our own services are faultless. Though the general standard of institutional care for the tuberculous here is high, even we are not without so-called sanatoria which have no diagnostic equipment, no facilities for active treatment, and no staff qualified to apply it if they had it, and whose patients are sent many miles away on the rare occasions when an *x*-ray film is thought necessary.

With the realization of the problems there was a growing feeling in several countries that the available beds were not being properly utilized, and a part of the plans for the future was to have centres to which patients would be admitted for primary observation and decision regarding the hospital to which they should go. Even more was it being realized that most of the local authorities who before the war had complete responsibility for providing tuberculosis services were far too small to perform such a function. We have seen this in England, and the regionalization of the hospital services is the natural outcome. This is happening in many countries. In Italy the provinces have been grouped into larger regions. In Czechoslovakia and Yugoslavia, too, there has been a regrouping in large regions to ensure a more equitable distribution of beds. In France also, where new legislation has brought radical changes in the tuberculosis services, these are now established on a regional basis, each region including several *départements*. The aim, as in England, is that each region shall provide a complete hospital service. The new Act stipulates that the hospital in the principal town of each *département* shall include a tuberculosis centre, with beds; where the town has a medical school the hospital unit becomes the regional tuberculosis centre.

The assumption by the State of much greater financial responsibility in provision of treatment for the tuberculous is an outstanding feature in the post-war services. The wartime increase in tuberculosis, in the absence of undue increase in other diseases except venereal disease, gave rise to the conception of this public health problem as a national emergency. The financing of sanatoria received radical reform. Before the war one of the causes of delay in sanatorium admission in France was the multiplicity of organizations, which made quite involved the problem of finding out before a patient went into sanatorium who would pay for him. Now if a bed is available the patient is admitted immediately; the payment of sanatorium expenses is incumbent on the *département* where the patient lives, unless eventually defrayed by a public or private body. All tuberculosis institutions qualify for a State subsidy, amounting to as much as 75% for building and equipment expenses. In many other European countries, including our own, the cost of institutional treatment is now entirely borne by the State.

Similarly, financial assistance to the tuberculous and their families, as a national scheme, was introduced in England in the middle of the war. As a basic principle it was recognized that the tuberculous patient must be relieved of economic anxiety, so that he might accept treatment for as long as is necessary, and so that his family might be protected. The measures introduced brought partial alleviation; but the scales were at a minimum subsistence level, and only certain patients qualified. Now since July 5, 1948, financial aid to tuberculous patients is covered by the National Assistance Board. In France since the liberation there has been increasingly generous social legislation, and part of it is directed to the new tuberculosis service. Previously patients received social insurance benefits for six months only. The new legislation grants the benefits of "prolonged illness" to insured tuberculous patients and to members of their families should they become tuberculous; during three years the patient gets all treatment expenses and half his salary. In Poland, Bulgaria, and Czechoslovakia similar new schemes of financial aid to the tuberculous have been introduced.

One concept, that of the so-called preventorium, which is practically unknown here, is prevalent in many European countries; the preventoria constitute sometimes more than 25% of the institutional tuberculosis accommodation. To these places are sent small children from tuberculous families, particularly when there is at home an infective patient who cannot or will not go to a sanatorium; for one or more years the children are kept away from the source of contagion, and then return at the end of their stay in the preventorium. Some were well organized; others we saw were barracks with children looking less healthy than those seen on the city streets. The problem is a thorny one. Certainly accommodation should be available for isolating children from households with an infective patient who cannot go away. However, one would like to be certain that every effort has been made to remove the infective case, since the preventorium is a second-best solution, returning the child to the infective household sooner or later, and leaving exposed the even more susceptible adolescents.

Dispensaries

The dispensary service is the basic diagnostic unit in European countries as it is here. But whereas here dispensaries have functioned for many years under the local authority, there they were directed before the war by a number of different organizations. In France, for instance, the 920 dispensaries had been created in the past 20 years mostly by local initiative, many by private organizations and Red Cross committees; there was no connexion with official centres; there was overlap in some areas, no service in others; financial arrangements and follow-up were extremely involved. The 1945 legislation makes the organization similar to what we have here; in each *département* now a list of dispensaries has been drawn up, and to each is ascribed a definite sector so that the districts concerned cover the whole *département*. A tuberculosis specialist is appointed to supervise all tuberculosis work in the *département*, and with him a specialized social worker. Each region has now a tuberculosis consultant with high qualifications. Another new feature is that many sanatorium medical officers attend at local dispensaries.

In Greece, too, the multiplicity of voluntary organizations was responsible for many gaps in the service. In whole large areas such as Epirus, with a population of over 300,000, there was not a single dispensary or institution for the diagnosis or treatment of tuberculosis. In Poland there was a basic organization, centred on the regions with their populations of about 1½ millions each, and numerous dispensaries in the districts, to a total of over 500 before the war. But here again, in the cities at least, there was a division between the local authority dispensaries and those belonging to the Social Insurance Organization, with little co-ordination between the two. The recent transfer of responsibility to the Ministry of Health is resolving a part of the problem, but the development of dispensary services is proceeding relatively slowly. The quality of the work in the hundreds of small country dispensaries varies

greatly; most of them are staffed by local practitioners who give one or two sessions a week and have no particular experience of tuberculosis. In Yugoslavia before the war there were some 50 dispensaries only, most of them poorly equipped; now there are 136, each of them with an *x*-ray unit and staffed by doctors who, while they have many other duties, have had at least three months of special training in tuberculosis work.

In Sweden the dispensaries were previously organized and financed by the National League Against Tuberculosis; now the expenses are chiefly defrayed by the State. In Belgium some dispensaries belong to the Œuvre Nationale Belge, some to other organizations; the Ministry of Health now covers 80% of dispensary expenses, compared with 50% pre-war. Denmark has a highly co-ordinated service with 85 dispensaries, of which 81 belong to the State. Every county, with about 150,000 population, has its own independent service, with tuberculosis hospital and dispensary working closely together; the specialist in charge of the hospital also serves the dispensaries in the neighbourhood. Great importance is attached to bacteriological examination, and in fact it is highly centralized, all cultures being done at the State Serum Institution in Copenhagen.

Staff

To the many problems of the tuberculosis services is added that of a lack of qualified personnel. Italy is the only country in which it is claimed that there is an excessive number of doctors, though even there adequate medical services are not readily available to large sections of the population. On the other hand, in Poland, where already before the war there were only 13,000 doctors for a population of 32 millions, the problem has become acute. In 1945 there were under 7,000, and in January this year 8,400—for a population of 24 millions. Moreover, they are concentrated in the towns, and there are rural areas with only one doctor serving 10,000 to 15,000 people. University medical courses were stopped throughout the war, and so, although the medical schools are now more than full and there are two new schools, there is little hope of the need being met before 1954 or 1955. There is a particular dearth of doctors with tuberculosis experience. Two-month postgraduate courses in tuberculosis are being held in all medical schools, but it is not easy to get doctors to attend these, as all are so busy. In Yugoslavia, also, the lack of doctors was a main obstacle to the programme; in 1945 there were only 25 tuberculosis specialists left of a pre-war total of 77. There, too, intensive three-month courses are being held for general practitioners, and three-year courses for the training of specialists. In France under the recent laws there is now provision for selection, by competitive examination, of physicians joining the dispensary service. Many more than before the war are engaged full-time. Physicians appointed to sanatorium posts are also now required to hold certain higher professional qualifications.

A nursing shortage is obvious in many countries, but nowhere has it had so severe an impact on the services as in this country. In Mediterranean countries nursing as we understand it does not exist in many places, and the work is done by nursing aids with little training. In many other countries there is a severe dearth of trained nurses, which was obvious before the war and has been made worse by the loss of so many during the occupation. Though many new training schools are being set up, the needs will not be met for many a year. However, it has been instructive to see how in some countries good nursing care is given in certain hospitals with a very small number of trained nurses and a sufficiently large number of domestic aids to carry out all duties except those requiring nursing skill. In our own country the number of nurses available would not rank elsewhere as a shortage, but thousands of beds are empty for "lack of staff," and the common waiting period for admission to sanatorium is six to nine months. This problem is so grave as to constitute by far the greatest obstacle to progress in our tuberculosis services to-day. In the present acute situation, at least a partial solution might be found in a revision of traditional ideas concerning division of labour between nursing and domestic staff (the revision could include a "job-analysis" on tuberculosis wards), followed by an imaginative effort to secure staff for hospital duties which do not require skilled training in nursing.

Rehabilitation

Rehabilitation services in Europe are for the most part rudimentary or non-existent. Countries are taking a great interest in rehabilitation projects, but economic circumstances are such that these schemes must take second place. One scheme is particularly worthy of mention, and deserves to be reproduced here—that of the tuberculosis service for students in France. It is a complete diagnostic, treatment, and rehabilitation service. The focus of the service is the Sanatorium des Etudiants in the French Alps above Grenoble. University students, young graduates, and doctors are accepted as patients; many of them have been diagnosed on routine examination at university. The State pays part or the whole of the cost of treatment, according to the patient's ability to pay. A basic aim is to maintain morale and so hasten recovery. The sanatorium employs a director of studies, who takes details of the level of studies of each patient who arrives, and together with the medical adviser decides how much and what type of work the student can do each day. According to the stage of illness, a student may be encouraged to do individual reading in bed, or take part in study circles, or attend lectures given in the sanatorium by visiting professors, or finally attend lectures on one to three days a week at the University of Grenoble. Lectures are relayed to the bedside for those who cannot get up. Each patient, in fact, gets individual attention as a student who happens to be ill; that is the constant approach. There is none of the mental paralysis one finds often elsewhere: the social and intellectual life of the sanatorium is remarkably lively—there are concerts, plays, and discussion circles, and the students even produce four times a year a good literary journal called *Existences*. The sanatorium is now only one of several institutions: one in Paris takes in students waiting for a bed, and other post-treatment hostels in Grenoble and Paris serve the needs of students between their leaving the sanatorium and their full recovery. In Paris there is in addition a "medico-social" restaurant, where special meals are served for students who have a medical recommendation from the dispensary set up by a Relief Committee. Belgium, Switzerland, Holland, and Poland also each have a special sanatorium for university students.

Routine Examinations

In several countries schemes for regular medical examination of university students have been introduced or extended since the end of the war, and we are falling far behind in this respect. In France yearly medical examinations of university students was introduced by a decree in April, 1946. *X*-ray examination has also been made compulsory for all teaching staffs—a measure entirely justified by the reports of minor tuberculosis epidemics discovered in school classes.

The examination of students is only a part of the work aiming at early diagnosis by routine examination which has been considerably extended since the advent of mass miniature radiography. This method has proved its value in the detection of undiagnosed lesions in large population groups, and there is no doubt now that it has an important place in tuberculosis eradication. Reports from services where annual examinations have been made have shown a falling incidence at successive annual re-examinations of a community, the fall being almost certainly due to the discovery of the early lesion with good prognosis, and the reduction of the infector pool. In England it has been developed as a national scheme, operated by as yet a limited number of local authorities; teams are trained centrally, and the technical level of work is relatively high. On the Continent it has been taken up by different organizations, and on an extensive scale in all countries I think except France; in fact, it has been adopted with almost embarrassing enthusiasm as in the first line of tuberculosis control. In countries which still have a very high prevalence of tuberculosis, and whose material resources are limited, mass radiography can for the time have only a small part in tuberculosis control; its role there can be to make spot surveys and so determine which population groups require prior attention in the tuberculosis programme. There is a danger at the moment in some countries that its excessive use in areas without adequate services may mean that other more fundamental work in tuberculosis control is being neglected.

B.C.G.

Another method of control that has been used widely since the end of the war is that of immunization against tuberculosis by B.C.G. vaccine. It was already being extensively used in Scandinavian countries. At the end of the war teams of the Danish Red Cross undertook B.C.G. vaccination in Poland, Hungary, and Germany. In 1947 it was decided by the newly formed Unicef (United Nations International Children's Emergency Fund) that, in addition to programmes of feeding and re-establishment of children's institutions and services, Unicef should continue and extend to several other countries the work started by the Danish Red Cross. This scheme is now in operation. Unicef furnishes supplies and equipment; Scandinavian teams do the initial field work; the Ministry of Health in each country furnishes local teams which will eventually take over the work; the World Health Organization assists with its advisory staff and will carry out a statistical analysis of the results. Finland, Poland, Czechoslovakia, Yugoslavia, Hungary, and Greece are taking part. By June 1, 1949, about six million tuberculin-negative children had been vaccinated. B.C.G. vaccination is being adopted with enthusiasm in these countries. One must hope that the development of basic measures of tuberculosis control will not be thereby neglected, for, even if the vaccine is as effective as its most ardent supporters claim, the basic tuberculosis services will still be required for many years to come.

International Services

The services described above have been those concerned specifically with tuberculosis. No doubt the measures taken to re-establish or improve the services are contributing to the post-war decline in tuberculosis mortality. But much of the decline, which in some countries started before the end of the war, and in nearly all countries has occurred since the war, may be attributed to the national and international services designed on a generous scale to protect the health of the peoples. In this respect it can be said that the work of Unrra in relief and rehabilitation and in the restoration of normal living was an important contribution to reduction of the tuberculosis rate.

Looking back on the work of Unrra in that post-war period, there is no doubt that it was a major achievement in international work. With all its faults, the organization carried out the task given to it by the United Nations—the task of relieving the most distressed areas in the war-ravaged countries, and of providing supplies to assist those countries to return to at least their pre-war standard of living. Because of it the dangers of famine and epidemics in the chaotic post-war period were averted, and with them the danger of another grave increase of tuberculosis.

Unrra, having provided immediate relief and the material for future reconstruction, was followed by other organizations operating under the United Nations; one of these is the World Health Organization. Established officially in 1948, WHO confirmed the decision of the Interim Committee, which had preceded it, regarding the priorities to be given to different diseases in the work of the organization. It was agreed without question that malaria, tuberculosis, and venereal diseases were the three main scourges demanding prior and special attention. An Expert Committee on Tuberculosis was formed, and held its first meeting in July, 1947. Among its recommendations to WHO were the following:

1. That travelling fellowships be awarded to countries most in need.

2. That the Tuberculosis Section prepare from time to time material on recent developments of special importance for the use of physicians in different countries who may request such information. Dr. McDougall, who heads the section, reports that there has been a great demand for data on tuberculosis mortality and morbidity rates, mass radiography, and B.C.G. (Many of the rates given in this paper are taken from the WHO *Epidemiological and Vital Statistics Reports* (1948).)

3. That demonstration teams shall be available, at the request of governments, for countries where new tuberculosis schemes are about to be introduced. In this connexion work has been done in China, Greece, Poland, and India.

4. That WHO should develop and recommend uniform procedures on such matters as the classification of tuberculosis, *x*-ray interpretation and mass radiography, bacteriological diagnosis, and evaluation of new chemotherapeutic agents such as streptomycin.

It is fully acknowledged by those working for WHO in this field that they have a relatively limited part to play in the overall campaign for reduction of tuberculosis prevalence; in their words: "Without progressive improvements in the purely public health field, and above all in the economic status of countries, the best efforts of tuberculosis workers can be of only limited significance" (McDougall, 1948).

Conclusion

Sir Wilson Jameson, in his Harveian Oration to this College in 1942, traced the phases of advance in social medicine, and showed how many of them resulted from the medical necessities of war. Similar great advances were already being made then, but he forecast also a different attitude from that following the first world war, in that there was even then in 1942 "everywhere a conviction that great changes lie ahead of us and a desire so to plan the measures designed to meet the national emergency that some permanent good may be derived from them when the world is once again at peace."

It is true that out of this last war, with all its catastrophes and refined barbarities, people have emerged with a deepened sense of national and international responsibilities: of national responsibilities because we learned in

time of stress to co-ordinate action in defence of the community, and methods dependent on bounty and charity have been replaced in many countries by the conception of the community's duty to protect itself as a whole and each individual who may suffer misfortune. Hence the general measures we have seen of co-ordination of the tuberculosis services, their financing by the State, free treatment, and financial allowances to the sick and their families. The war awakened also a sense of international duty. It had brought together peoples who had lived in ignorance of each other, and, having assumed duties towards them in wartime, the projection into peacetime was natural, so that well before the war ended there were being laid the plans of international relief and co-operation which finally materialized in Unrra and then in the World Health Organization.

The wartime rise and the post-war fall in tuberculosis provide evidence that constitutes an indictment of existing social services when one relates them to what they should be. That tuberculosis is related to social conditions was already known, but the wartime evidence showing precise points of rise and fall is outstanding. With such evidence as this, and with the knowledge of rates obtained in countries such as Denmark, no country with a tuberculosis rate anywhere above the lowest rate yet recorded can afford not to make a continuous attack upon the disease and upon the conditions that favour its development. It has been said that "public health is purchasable, and that within natural limitations any community can determine its own death rate" (Biggs, 1911). Certainly of tuberculosis it is true. The more sore the economic plight of a country, the less it can afford to tolerate a preventable disease which affects the most active members of the community, and it is particularly in such countries that the tuberculosis programme should have a high budget priority.

We have the good fortune to be living through an age of extraordinary achievement. In the 80 years since the discovery of the bacterial sources of disease the advancement of knowledge in medicine alone has raced far ahead of our application of it to human welfare. Wars have arrested and then spurred on our progress. The means for attack on tuberculosis can be clearly seen; if the necessary measures are taken, and given a long enough respite from mutual massacre, there is no reason why this disease which has plagued the continent of Europe for many hundreds of years should not be almost eradicated before this century is out.

Among the many people to whom I am indebted for assistance in preparation of this paper I am particularly grateful to those in the Departments of Health of many European countries who have supplied information in person or by correspondence, and also to Dr. J. B. McDougall, of the World Health Organization.

VARIATIONS IN BACTERIOLOGY OF THROAT AND RECTUM OF INFANTS IN TWO MATERNITY UNITS

BY

ALLAN M. McFARLAN, M.A., M.B., B.Chir.

*Reader in Human Ecology, University of Cambridge**

P. B. CRONE, M.D.

AND

G. H. TEE, M.A., M.R.C.S., L.R.C.P.

(From the Public Health Laboratory Service, Cambridge)

This investigation was prompted by the suggestion that gastro-enteritis in infants might be due to bacteria usually regarded as normal inhabitants of the throat or intestine (Cruickshank, 1946). Particular strains or types of these organisms might be concerned; for instance, a serological type of coliform bacillus such as has been isolated from infants with diarrhoea (Bray, 1945; Giles and Sangster, 1948), and strains of *Streptococcus faecalis* which are active producers of tyrosine decarboxylase (Gale, 1944). It was also suggested (G. S Wilson, 1947; personal communication) that *Staphylococcus pyogenes* might be the cause of some outbreaks of neonatal diarrhoea. The laboratory studies necessary to establish the serological type of coliform bacilli, the tyrosine decarboxylase activity of streptococci, and the phage type of staphylococci require considerable time and experience. In field investigations of an outbreak of neonatal diarrhoea it would be helpful if simple bacteriological methods could be used to give a rapid indication that coliform bacilli, faecal streptococci, or aureus staphylococci were present in cases with greater frequency than in healthy infants. Some observations suggested that this might be the case.

It had been noted in some outbreaks that coliform bacilli were often isolated from throat swabs (J. Taylor, 1947; personal communication) and in others that streptococci

*Working for the Public Health Laboratory Service.

were present in greater abundance than usual in films and cultures of faeces (E. F. Gale, 1947; personal communication). Numerous surveys of the incidence of *Staph. pyogenes* in older age groups have revealed differences which suggest that it might be useful as a base-line for the study of epidemics of neonatal diarrhoea and vomiting to determine the incidence of the organism in newborn infants. In this investigation, therefore, simple bacteriological methods were used for routine examinations of throat and rectal swabs from infants. A general survey of the organisms in cultures was made and three points were particularly studied: (1) the frequency with which coliform bacilli were isolated from throat swabs; (2) the frequency with which colonies of *Str. faecalis* outnumbered those of coliform bacilli in cultures of rectal swabs; and (3) the frequency with which *Staph. pyogenes* (aureus) was isolated from throat and rectal swabs.

Technique

Infants in two maternity units were studied. Details about the two units, A and B, are given by Dr. Janet Roscoe at p. 1144 of this issue in a report on the incidence of infections in them. Apart from one outbreak of mild staphylococcal infections of eyes or skin there were only sporadic infections in the infants and no severe diarrhoea or vomiting. At Unit B weekly swabbings of all infants were examined from April to July, 1947, and from October, 1947, to April, 1948. At Unit A all infants in one of the four wards were swabbed each week from May to July, 1947, and from November, 1947, to April, 1948.

All swabs were taken by Dr. Roscoe, with care to swab the posterior pharyngeal wall and to avoid contamination of the rectal swab by the circumanal skin. The swabs were plated within a few hours of the time they were taken. Throat swabs were plated on horse-blood-agar plates which were incubated aerobically overnight and examined for aureus staphylococci, coliform bacilli, and other organisms. Rectal swabs were plated on horse-blood-agar plates which were incubated anaerobically for 18 hours in the first three months of the investigation and from November onwards for 42 hours before examination. The growth of coliform bacilli and streptococci was recorded as +, ++, or +++, and the presence of other organisms was noted. When the estimate of streptococcal colonies was higher than that of colonies of coliform bacilli, streptococci were said to be present in excess. Rectal swabs were also plated on 7.5% salt-agar plates which were incubated aerobically overnight before examination for aureus staphylococci. Films from rectal swabs were stained by Gram's method and examined for lactobacilli, Gram-negative bacilli, and Gram-positive cocci.

From time to time the following tests were done: coagulase tests on aureus staphylococci; V.-P., M.R., citrate, indole, and 44° MacConkey reactions on coliform bacilli; grouping of streptococci. Some streptococci isolated at the end of the investigation were tested for tyrosine decarboxylase activity.

Results

From throat swabs albus staphylococci and viridans streptococci were almost always isolated; pneumococci were occasionally found, as were haemolytic streptococci. None of the latter reacted with Group A, C, or G sera; one strain tested with Group D serum was found to belong to that group. The frequency of isolation of aureus staphylococci and coliform bacilli will be described later. All strains of aureus staphylococci tested were coagulase-positive. The majority of coliform bacilli tested were found to be faecal *Bact. coli*, a few were *Bact. aerogenes* or irregulars.

From most rectal swabs blood plates showed colonies of coliform bacilli and streptococci. The streptococcal colonies were readily recognizable as low convex bluish colonies about 2 mm. in diameter, usually with greening under them, sometimes with no change in the blood and occasionally with β-haemolysis. Tests of colonies with the different types of haemolysis showed that they were Group D. At the end of the investigation 18 colonies of Group D streptococci isolated from rectal swabs were tested for tyrosine decarboxylase activity. One was inactive. The other 17 were active producers of the enzyme; 10 of them were picked from cultures of two infants (five each), three from a third infant, and four from four other infants. A few colonies of clostridia were occasionally seen on the blood plates. Proteus was very rarely present. Lactobacilli were isolated, but irregularities in the frequency of their appearance and in the number of colonies relative to other organisms were such that analysis of the results was not made.

On MacConkey plates non-lactose-fermenting colonies of coliform bacilli were uncommon and the organisms in such colonies were not salmonellae or shigellae. Colonies of coliforms and cocci appeared in the same relative numbers on MacConkey plates as on blood plates of the same specimen, but colonies of streptococci could not be distinguished from those of other cocci.

Films of faeces stained by Gram's method usually showed large numbers of Gram-positive rods resembling Cruickshank's (1925) drawings of lactobacilli. Coliform bacilli were less frequently seen, and Gram-positive cocci, usually in pairs, still less frequently. Gram-positive rods resembling bacilli or clostridia were occasionally seen.

Differences between Cultures from Infants of Different Ages

In cultures from infants during the first 24 hours of life growth was scanty or absent, and the percentage of swabs from which the organisms listed in Table I were isolated

TABLE I.—*Percentage of Positive Cultures from Infants on Each of the First Five Days of Life*

	Age of Infant in Days				
	0	1	2	3	4
Throat swab:					
Aureus staphylococci ..	19	13	17	25	27
Coliform bacilli	0	9	14	17	17
Recta /swab:					
Coliform bacilli	22	60	74	86	75
Streptococci	26	76	69	92	85
Excess streptococci	15	56	31	36	36
Aureus staphylococci ..	8	17	15	18	26
No. examined ..	27	24	42	36	41

was with one exception lower than on subsequent days. The exception was that aureus staphylococci were found in the throat almost as often on the first day of life as on later days. The results from infants aged 1, 2, 3, or 4 days showed an increase in the percentages of positive results during the first three days, and figures for the 4-day-old infants were approximately equal to those for 3-day-old infants. Subsequent comparisons were therefore made on results of swabs from infants aged 3 or more days.

The stained films of faeces showed that lactobacilli were present in an increasing percentage of infants on each of the first five days of life, the percentage positive on each day being 4, 14, 49, 60, and 82.

Differences between Cultures from Infants in Unit A and Unit B

Cultures were made from 187 infants aged 3 or more days in Unit A and from 198 infants aged 3 or more days in Unit B. The last column of Table II gives the percentages of these cultures from which certain bacteria were isolated, and the other columns give the percentages for successive time periods during the investigation. These periods were the result of grouping successive weekly swabbings so as to give, when possible, about 20 or 30 results in each period.

No. examined ..	36	17	26	22	23	28	19		27		198

All these infants received fluids or complementary feeds during the first few days of life.
Mild staphylococcal infections occurred in infants at Unit A in mid-May, July, and late February and March, and in Unit B in mid-May and January.
The following differences between the percentages of totals were statistically significant:
Throat swabs: aureus staphylococci D/SE = 3·8; coliform bacilli D/SE = 6·4.
Rectal swabs: coliform bacilli D/SE = 4·1; excess streptococci D/SE = 5·0; aureus staphylococci D/SE = 2·6.

Aureus staphylococci were less often cultured from both throat and rectal swabs taken in Unit A than from those taken in Unit B. The figures for successive time periods showed that in both units these organisms were more often isolated at times when mild staphylococcal infections were occurring in the infants. Not enough data were available to show whether an increased prevalence of the organism preceded the appearance of infections as suggested by Allison and Hobbs (1947) or occurred rapidly at the time when the first case was noted. The differences in the frequency with which aureus staphylococci were isolated in the two units can be attributed to a greater exposure of infants in Unit B. All infants in Unit B were in the same nursery as the infected infants, whereas in Unit A swabs were taken from infants in four nurseries and some infants were in nurseries where there were few or no cases. Infants in Unit B were often kept in the unit longer than those in Unit A. The environmental conditions in Unit B (see Roscoe, p. 1144 of this issue) were more likely than those in Unit A to allow the spread of organisms from infant to infant.

Coliform bacilli were less often found in the throat and rectal swabs from Unit A than in those from Unit B. The percentage of cultures of rectal swabs yielding streptococci was similar in the two units. The cultures of rectal swabs in which streptococcal colonies were in excess of those of coliform bacilli formed a greater percentage of all cultures in Unit A than in Unit B. The percentage of cultures with excess streptococci increased in both units in November, when the time of incubation of the cultures was increased from 18 to 42 hours. The difference between the units was maintained throughout the investigation, though it was less in the later periods. The plates on which streptococci were present showed an excess of the organism more often in Unit A than in Unit B (Table III).

TABLE III.—*Percentage of Cultures of Rectal Swabs with Streptococci in which Streptococcal Colonies Outnumbered Colonies of Coliform Bacilli*

	Period										
	1 April-May	2 May-June	3 June-July	4 October	5 November	6 December	7 January	8 February	9 March	10 April	Total
Unit A		27			55		48	47	43	52	44
Unit B	4	6	8	5	29	35	37		37		19

In films of faeces, lactobacilli were found in 93% of 187 examined from Unit A and in 71% of 198 examined from Unit B. Differences noted between the units were that in Unit B there was (1) a higher percentage of cultures yielding coliform bacilli, (2) a lower percentage of cultures with excess streptococci, and (3) a lower percentage of films showing lactobacilli. The explanation which suggested itself was that these differences were due to the fact that a greater proportion of infants in Unit B than in Unit A were receiving complementary feeds or were artificially fed at the time of examination. Below is presented an analysis of data which were available on the effect of different feeding regimes on the bacterial flora.

Differences between Cultures from Infants on Different Feeding Regimes

Cultures were examined without knowledge of the feed given to the infant. With the help of Dr. Roscoe's data the bacteriological results were analysed to show results for infants on different feeding regimes.

In Unit B among 33 infants who were artificially fed the percentage of cultures of throat swabs yielding coliform bacilli was 60, as compared with 36% in 66 infants receiving complementary feeds and 29% in 42 infants who were breast-fed at the time of examination but had received fluids during the first few days of life.

A regime of breast-feeding with no additional fluid or food was introduced in two wards of Unit A in January This made it possible to compare the bacteriology of the throat and rectum of completely breast-fed infants with that of three groups of infants. The first group had received complementary feeds during the first few days of life but were breast-fed when specimens were taken; the second group were receiving both breast and complementary feeds; and the third group were artificially fed at the time of examination.

The results (Table IV) varied in a similar way to those already mentioned. Coliform bacilli were not found in the throats of 65 breast-fed infants; they were present in two of 28 infants who had received complementary feeds but were breast-fed when examined, in four of 28 infants who were receiving both breast and complement, and in

TABLE IV.—*Percentage of Positive Results in Infants in Unit A Aged 3 or More Days on Different Feeding Regimes*

No. examined ..	65	28	28	24

tour of 24 infants who were artificially fed. Only one of the 10 infants whose throat swabs yielded coliform bacilli had vomited, and that one on a single day only. Three of the other nine had oral thrush. The remaining six were apparently perfectly healthy infants. In cultures of rectal swabs coliform bacilli were isolated less often from infants who received breast milk only and with increasing frequency in the other three groups : (1) those solely breast-fed but having received complement, (2) those receiving breast and complement, and (3) those artificially fed. Streptococci were found in approximately the same percentage of cultures from all four groups, but their colonies were in excess of the colonies of coliform bacilli in a higher proportion of cultures from infants who were receiving breast milk only at the time of examination than in cultures from infants receiving artificial feeds solely or as complement.

The absence of coliform bacilli in the cultures of throat swabs from 65 infants who were entirely breast-fed and the isolation of coliform bacilli from the throats of a number of infants who had received or were receiving complementary feeds (Table IV) suggested that these bacilli had been introduced with the feeds. In accord with this suggestion were the higher percentages of isolations of coliform bacilli from rectal swabs of artificially fed infants (Table IV) and the more frequent detection of Gram-negative bacilli in stained films of swabs from the same group of infants (Table V). Tests were made on several

TABLE V.—*Percentages of Films from Rectal Swabs showing Different Numbers of Organisms*

No. examined		59	30	30	30

samples of the ingredients of the complementary feeds and of feeds prepared in the ward, but coliform bacilli were not isolated. This did not, however, rule out the possibility that bacilli were introduced with some feeds. It is probable also that there were alterations in the intestinal environment of the artificially fed infants which favoured the growth of coliform bacilli. The coliform bacilli isolated from the throat may have been merely transients there, deposited from feeds or by regurgitation.

The Gram-stained films from rectal swabs provided further evidence (Table V) of differences in the intestinal flora of infants receiving different feeds. Lactobacilli were less often seen, and far less often seen in large numbers, in the films from artificially fed infants than in films from infants receiving breast milk only at the time of testing. The converse was found for Gram-negative bacilli and Gram-positive cocci.

Discussion

The simple cultural methods which we used showed the following maximum percentages of isolations from infants aged 3 or more days : (1) 54% for coliform bacilli from the throat in Unit B and 10% in Unit A ; (2) 47% for excess streptococci from rectal swabs ; (3) 40% for aureus staphylococci from the throat and 50% from rectal swabs at times when no staphylococcal infections were occurring in infants. Films of faeces showed lactobacilli in large numbers in 60%, Gram-negative bacilli in 20%, and Gram-positive cocci in 15%. Figures of this order suggest that the methods might indicate the more frequent presence of large numbers of these organisms in infants with diarrhoea as compared with controls. Analysis of our results shows that in making these comparisons attention must be paid to the age of the infants and to the method of feeding, since these factors affect the results.

The methods used in this study might therefore, if applied to field investigations of epidemics, give a rapid indication of an abnormality in the bacterial flora of the cases. This would aid in deciding on the lines of search for the sources of an infection and its mode of spread. Subsequent typing of strains would be essential in order to establish the identity or difference of strains isolated from patients and other sources. The simple cultural methods which were used may be successful when applied to cases in which the infecting organism is likely to be present in large numbers. In the search for carriers and in the bacteriological diagnosis of some cases selective media may be necessary. For example, Robertson's meat medium with 10% of added NaCl (Maitland and Martyn, 1948) would be valuable for isolating staphylococci from faeces. The use of selective media would increase the percentages of positive results above those reported here and might reduce or eliminate differences such as we found. It does, however, appear from our results that the combination of simple cultural methods with rough quantitative estimates would be a practicable, and possibly a useful, method in field investigations of epidemics of neonatal diarrhoea.

Summary

In order to obtain a base-line for the study of epidemics of neonatal diarrhoea simple bacteriological methods were applied to the examination of throat and rectal swabs from infants in two maternity units. During the 12 months of the investigation the incidence of infections was low.

Variations were noted in the percentages of cultures from which coliform bacilli, faecal streptococci, and aureus staphylococci were isolated. Differences were found between the flora of infants examined during the first four days of life. The incidence of aureus staphylococci was higher at times when staphylococcal infections were occurring. Coliform bacilli were more often isolated from the throats of infants who were receiving complementary or artificial feeds at the time of examination than from the throats of breast-fed infants. In cultures of rectal swabs streptococci were more often present

in excess of coliform bacilli when specimens were taken from infants receiving artificial feeds than when they came from infants who were receiving breast milk only at the time of examination. Although coliform bacilli were not isolated from some feeds and ingredients tested, the differences observed suggested that the bacilli might have been introduced with the feeds. Whether they were introduced in that way or from some other source, the higher incidence of coliform bacilli and their preponderance in the faeces of artificially fed infants may have been due to changes in the intestinal environment of these infants.

Films from rectal swabs stained by Gram's method were examined and rough quantitative estimates were made of the numbers of lactobacilli, Gram-negative bacilli, and Gram-positive cocci. Variations were found with infants of different ages and on different feeding regimes.

It is suggested that the methods used in this study might be applied to field investigations of outbreaks of neonatal diarrhoea as a preliminary to typing of organisms and that they might help to direct investigations of the source and mode of spread of infection in the infant community.

This study was planned as part of a combined clinical and bacteriological study of infections in newborn infants. We wish to thank Dr. Janet Roscoe for taking swabs and for keeping clinical records for use in the analysis of the bacteriological findings. We are also indebted to Dr. Joan Boissard for grouping some streptococci in the early part of the investigation.

INCIDENCE OF INFECTIONS IN INFANTS IN TWO MATERNITY UNITS

BY

JANET D. ROSCOE,* M.B., B.S., D.C.H.

First Assistant, Paediatric Unit, United Cambridge Hospitals

Since May, 1947, all infections and illness, however trivial, occurring in the babies of two maternity units in Cambridge have been carefully recorded. Unit A took all normal obstetric bookings; Unit B took the abnormal obstetric patients. In each ward day-by-day charts have been kept of the number of mothers, the number of live births, the number of babies in the nursery, and the number of these which were premature. Any infection which has occurred among the babies, the mothers, or the staff has also been recorded on these charts. Bacteriological investigations of the infected cases were undertaken by the Public Health Laboratory Service, Cambridge. In addition throat and rectal swabs of every baby in the ward were taken at intervals throughout the year. These results form the basis of a separate report by McFarlan *et al.* (see p. 1140 of this issue).

I saw all the infected babies. A detailed analysis has been made covering the period from May, 1947, to April, 1948. The infection rate in Unit A was 8.3% (104 infected babies in 1,257 live births); in Unit B the infection rate was 10.3% (19 infected babies in 185 live births) (Table I). It should be emphasized that the slightest evidence of infection was recorded as such; the smallest single pustule, or a sticky eye if it remained sticky for longer than 24 hours, was recorded even if no pathogen was grown from the swab.

*This work was undertaken while holding a grant from the Medical Research Council.

TABLE I.—*Analysis of Infections*

	Unit A					Unit B

Live births	391	343	367	156	1,257	185

* Three babies had two infections at the same time—two in ward VIIB and one in Unit B. The totals are therefore adjusted accordingly.

Table II shows the distribution of infections in Unit A according to wards, with the number of live births, by four-week periods. It will be seen that the infections occurred more or less sporadically throughout the year, apart from a sudden increase in VIIB early in 1948, when there was a small epidemic of spots and sticky eyes at the beginning of March. This was controlled by barrier nursing precautions and the use of penicillin and sulphadimidine (sulphamezathine). None of the babies affected was ill and the nursery was not closed.

I. = Infections. B. = Births.

Very few upper respiratory tract infections and no intestinal upsets amongst the mothers or staff were reported during the year under review. It seems likely that this may have been a factor in the reasonably low infection rate amongst the infants. That there was no consistent rise of infections corresponding with increased business of the ward, as shown by live births, means no more than that there was adequate staff and space for potential cross-infection to remain controlled.

In Unit A 20 infant deaths occurred during the year covered; none was attributable to infection. Post-mortem examinations were made on 10 of these. Seven of the others were very premature (2–3½ lb. (0.9–1.6 kg.) birth weight) and died within a few hours of birth; the other three had severe congenital abnormalities and died within a few days. In this unit the only infection which caused serious illness was pneumonia; two babies were affected, one being a premature infant of 3 lb. (1.36 kg.), but both eventually recovered.

In Unit B three babies recovered from one infection only to get another later; these were counted as separate infections: the total of 19 infections therefore implicates only 16 babies. These infections also were spread fairly evenly through the year. One death was attributable to infection: the baby was the eighth child of the family and obviously premature, though the dates were unreliable and birth weight was 5½ lb. (2.5 kg.). He never would suck and had to be tube-fed. When a fortnight old he suddenly lost 9 oz. (0.25 kg.) in 24 hours and showed signs of otitis media. *Staph. aureus* was grown from the throat. In spite of penicillin, sulphadimidine, and intravenous therapy for 12 days, he died. Post-mortem examination revealed pus in both mastoid cavities from which *Bact. coli* was grown. The other two cases of otitis media occurred four months later at ten days' interval; one was a premature baby of 3 lb. 2 oz. (1.39 kg.) whose ear discharged spontaneously. Neither appeared seriously upset by their infection, and both cases cleared satisfactorily.

Accommodation and Staffing

These have such an effect on cross-infection in any hospital that it is important to give details for comparative purposes. From the following description it will be apparent that the staff were working under conditions less than ideal.

Unit A

Accommodation.—Fifty-six mothers could be accommodated. Only normal cases were booked. These were divided between four wards as follows:

Ward	Mothers	Floor Area of Nursery	Potential Area per Cot
VIIA ..	14	216 sq. ft. (12 × 18)	15·4 sq. ft.
VIIB ..	14	384 sq. ft. (12 × 32)	27·4 sq. ft.
IV ..	16	1,152 sq. ft. (24 × 48)	72 sq. ft.
VI ..	12	270 sq. ft. (15 × 18)	22·5 sq. ft.

Ward VI was regarded as an overflow; it was opened in June, 1947, and was closed twice during the year under review for two or three weeks each time. It had not its own labour ward; women were therefore delivered in Ward IV or VIIA, the mother and baby then being transferred to Ward VI at once. Each ward had its own nursery in which the babies were nursed in separate cots. It will be realized that the potential cot space varied greatly in the different wards. Ward IV had plenty of space; in Wards VIIB and VI there was very little space between each cot; and in Ward VIIA the cots almost touched. All the nurseries had good windows. No provision was made for the isolation of infected or premature babies, unless by chance one of the side rooms, of which there were two each on all the wards but VI, happened to be available. Infected babies were therefore usually nursed in a corner of the nursery.

Staff.—Each ward had one sister and one staff nurse; in addition there were pupil midwives (undertaking the first six months of their C.M.B. training)—six on Ward IV and four on each of the other wards. All the nurses attended the mothers and the babies; there were no "nursery nurses" who looked after the babies and no one else. Each ward had also one nursing orderly and one charwoman. The night staff consisted of one sister, four staff nurses, three pupil nurses, and eight assistant nurses. On any one night a total of nine or 10 nurses were distributed round the four units. There was one resident house-surgeon. The medical officer lived out and paid a daily visit.

Nursery Technique.—Masks of one sort or another had to be worn by anyone entering the nursery; but in fact the mask "drill" had been somewhat neglected and masking had become perfunctory. Gowns were not worn. At birth sulphacetamide drops were instilled into the eyes: the baby was then bathed and weighed. Two days later it was bathed and weighed again, and thereafter daily. Each nursery had, next to the basin, a bathing-table covered with a mackintosh and sheet, on which the baby was placed on his own towel for bathing or changing. The basin was mopped round with "ibcol" between each bathing. The buttock ointment was kept in a communal jar but was extracted with a small square of lint, a separate piece for each baby, so that the nurses' fingers should not touch the ointment. After changing, the soiled napkins and clothes were dropped in a bucket; after feed-time these were taken to the sluice-room, where the nurses rinsed them in plain water before sending them to the common laundry. Babies were taken to and from their mothers, one under each arm, at feed-times. Mothers did not mask unless they had a cold or sore throat. There was no special routine care of mothers' breasts or hands. The nursery floors were swept once a day.

Feeding.—Until January, 1948, all babies were offered, after each breast-feed for the first three days of life, a complementary feed of a dried milk preparation which, when reconstituted, had a relatively high carbohydrate percentage. This was given by a nurse or the mother by cup and spoon. From January, 1948, two wards continued this practice, while the other two gave no complementary feeds or fluids except in special cases. When complementary or supplementary feeds were used they were made up in the ward kitchen. There was no milk kitchen. Bottles and teats were boiled in a fish-kettle on the gas-stove.

Unit B

Accommodation.—This unit was the maternity unit in the general hospital. The intention was that only abnormal obstetric cases should be admitted. There were two lying-in wards, taking six and four women respectively. The only nursery was very small (10 ft. 6 in. by 13 ft.—3.2 by 3.96 m.) with one window facing north. There were nine cots, which were packed in threes on three trolleys; the sides of the cots were touching and there was barely 1 ft. (30 cm.) floor space between the trolleys. Infected or premature babies could not be properly isolated; the bathroom (sister's office) was used in conjunction with an oxygen box as the only place available away from the nursery.

Staff.—A nursery nurse attended to the babies, but when she was off duty or needed assistance one of the pupil nurses on the unit came into the nursery to help. At night there was only one nurse for the whole unit; she attended to the mothers and babies. One ward maid "charred" for the unit. A paediatrician attended daily.

Nursery Technique.—Masks were worn in the nursery, but here again masking had become careless. There was one gown per infant, which was worn for washing or changing or artificial-feeding that infant; when taken off it was rolled up and put on top of the baby's basket on the trolley underneath the cots. These baskets were therefore closely packed. Babies were weighed at birth, again on the third day, and thereafter daily. They were bathed at birth, then "topped and tailed" daily until the cord came off, and thereafter were bathed daily. Bathing and changing were done on the nurse's lap. The floor of the nursery was polished parquet. During the daily sweep and polish the trolleys were pulled out into the corridor and the cots on them covered with a single layer of butter muslin. Otherwise the technique was similar to that described for Unit A.

Feeding.—According to the mother's condition the baby was put to the breast after 24 to 48 hours. Until then boiled water was given. This, and the artificial feeds given when necessary, were prepared in the ward kitchen. Bottles and teats were boiled in a fish-kettle on the gas-stove.

Discussion

It is interesting to compare infection rates amongst the babies of maternity units in different parts of the country from time to time. Various earlier reports (Henderson, 1943; Corner, 1946; Department of Health for Scotland, 1947) have recorded infection rates for neonatal units of

between 20% and 30%. While the present report was in progress another was published (Frazer, 1948) which is salutary to all who had been achieving rates of about 10%, for in Belfast the commendably low figure of under 3% was reached. So far as can be ascertained the criteria of infection used by each observer were similar to those employed at Cambridge.

It will be appreciated from Table III that eye infections are usually the most prevalent and skin infections next so. However, Frazer's figures and those of Unit B show skin

TABLE III.—*Records of Neonatal Infection Rates*

	Cambridge 1947–8		Edinburgh (Henderson, 1943) 1940–2	Bristol (Corner, 1946) 1944–5		London St. Heller* 1945	Belfast (Frazer, 1948) 1946–7
	Unit A	Unit B		A	B		
Total live births	1,257	185	8,075	3,344	3,190	1,293	2,274
Total infections	8·28%	10·28%	29·8%	25·9%	29·7%	21%	2·77%

Thrush ..	0·32%	0	4·9%				0·35%

* Department of Health for Scotland Report, 1947, p. 24.

infections to be nearly three times more common than eye infections. It is therefore interesting to conjecture whether the covering of the cot with gauze as practised by Frazer, which minimizes dust-borne infection, and the removal of the babies during the cleaning of the ward in Unit B in Cambridge had any part in the reversal of the usual finding.

The incidence of infections in hospital nurseries must be related to the quality and number of staff available. However, it would also seem likely that the architectural arrangements of the unit are of great importance. In the Belfast Maternity Home (Frazer, 1948) the basic units accommodated five or six mothers and babies, and the number of deliveries was such that a unit could be filled within 24 hours, allowing a thorough cleaning and airing of each unit for 24 hours between each intake. These arrangements would seem to be a factor in reducing cross-infections. These small units are very different from the large nursery for 50 babies described by Corner, even though the Bristol nursery was partially divided into three sections. In the Edinburgh nurseries, on which Henderson reported, a large number of babies are also collected in one room (personal communication).

These observations suggest that one way of reducing the hospital neonatal infection rate would be to reduce the number of babies in each nursery unit. By reducing the infection rate among newly born infants the death rate from infection in this age group should also be reduced. Infections are responsible for over 25% (Department of Health for Scotland, 1947) of neonatal deaths, and they are the most readily preventable cause.

I would like to thank Dr. Allan McFarlan, Dr. French, and the staff of the County Maternity Unit for their help and co-operation.

THE RELATION OF STAPHYLOCOCCUS PYOGENES TO INFANTILE DIARRHOEA AND VOMITING*

BY

G. MARTYN, M.R.C.S., L.R.C.P., D.P.H.

Research Fellow in Child Health, University of Manchester

(From the Department of Child Health and the Department of Bacteriology, University of Manchester)

The aetiology of infantile diarrhoea and vomiting remains obscure despite the efforts of many investigators. Amongst the many suggested causative bacterial agents mentioned is the staphylococcus. The purpose of this paper is to present the findings in an investigation to determine whether *Staphylococcus pyogenes* was a possible direct cause of the gastro-intestinal condition. The staphylococcus in relation to parenteral infection as a cause of diarrhoea and vomiting is not considered.

Draper and Brown (1946) recorded the presence of *Staph. aureus* in the stools in 26.5% of infants aged 0–1 year suffering from enteritis. One death occurred, in a child 8 months of age who had had a history of diarrhoea for six weeks before admission to hospital and died nine days later; the faeces contained pus and mucus. Felsen and Wolarsky (1942) reported an outbreak of epidemic diarrhoea of the newborn in 19 babies; they found *Staph aureus* in pure culture in two cases, and it was the predominating organism in a third case. These authors suggested that the presence of *Staph. aureus* was significant, but they were uncertain whether their evidence was sufficient to incriminate any single bacterial agent. Kramer (1948) reported a fatal case of enteritis in a child aged 6 weeks, and described the condition as one of staphylococcal enteritis on the finding of a coagulase-positive streptomycin-resistant *Staph. aureus* from the terminal ileum at necropsy. *Staph. aureus* was not cultured before the child's death.

Crowley *et al.* (1941), in their investigation of epidemic neonatal diarrhoea in maternity hospitals, found a coagulase-positive *Staph. aureus* in two cases in a series of 10 infants. They concluded from the evidence that there was nothing to justify the claim that the staphylococcus was anything more than a possible cause in some outbreaks. Taylor *et al.* (1949), in a series of 19 babies in two outbreaks of infantile diarrhoea and vomiting, found *Staph. pyogenes* in the stools on six occasions, and showed by phage-typing that the staphylococci did not belong to the types commonly present in staphylococcal food-poisoning. Because they found a low incidence and a sparsity of staphylococci in rectal swabs they discontinued further phage-typing.

The incidence of staphylococci in the stools of normal infants has been recorded by Duncan and Walker (1942), who found *Staph. aureus* in 74.4% of 61 newly born infants (method of isolation not stated), and by Martyn (1949), who, using a selective medium for the isolation of staphylococci, reported the presence of *Staph. pyogenes* in 50% of 130 healthy infants aged 0–7 days. Crowley *et al.* (1941) isolated *Staph. aureus* once in 57 normal breast-fed infants aged 3–23 days.

*This work was undertaken whilst holding the Cow and Gate Research Fellowship in Child Health, University of Manchester.

The Present Investigation

This paper records the results of an investigation into the incidence of *Staph. pyogenes* in the stools (*a*) of infants in hospital suffering from diarrhoea and vomiting, (*b*) in infants in hospital not suffering from gastro-intestinal symptoms, and (*c*) in a number of healthy babies attending a child-welfare clinic. The last two groups were examined to serve as controls.

All the infants in this series were aged between 2 weeks and 1 year. The majority of them were in the age group 1–3 months. The investigation was carried out between October, 1948, and July, 1949, and includes cases from four hospitals.

Bacteriological Methods.—Rectal swabs from the infants were plated as soon as possible after collection on horse-blood-agar plates and inoculated into a 10% NaCl meat medium recommended by Maitland and Martyn (1948) as being selective for staphylococci. All staphylococci isolated were tested for coagulase production; all positive strains are referred to as *Staph. pyogenes*, and these strains were tested for sensitivity to penicillin (40 units per ml.) and streptomycin (1,000 units per ml.), using soaked strips of filter-paper laid over 18-hour broth-culture streaks of the organism on agar plates. In addition all *Staph. pyogenes* strains were bacteriophage-typed, using the series of phages in routine use at the Central Public Health Laboratory, London. The strains classified as non-typable were tested against all the staphylococcal phages. In every case strains were tested against Kreuger phage.

Results of Culture.—Cultures were made from 119 infants with diarrhoea and vomiting, from 78 infants in hospital with no gastro-intestinal symptoms, and from 44 healthy infants attending a child-welfare clinic. The results are summarized in Table I. The incidence of *Staph. pyogenes* in cases (44.5%) and in controls (46%) showed a close similarity. There was a low incidence of streptomycin-resistant strains, only four being isolated. The frequency of penicillin-resistant strains was little different in cases and controls in hospital, but was higher in the out-patient controls; the difference is not, however, statistically significant. In Table II the incidence of bacteriophage types of the *Staph. pyogenes* strains isolated is recorded; the nomenclature, as already stated, is that used by the Central Public Health Laboratory. The distribution of types and the proportion of non-typable strains was similar for cases and controls. It is noteworthy that one type (47) accounted for almost half the typable strains. This type was also found to be prevalent in the staphylococci isolated from healthy newborn infants (Martyn, 1949), the strains having been typed after publication, and nearly all these type 47 strains were penicillin-resistant. Of the 38 strains of phage type 47, 26 were penicillin-resistant. Type 6/47 is recorded five times in the two groups: this type has been shown by Allison (1949) to be often associated with staphylococcal food-poisoning. There were 20 non-typable strains.

TABLE I.—*Incidence of Staph. pyogenes in Cases of Infantile Diarrhoea and Vomiting and in Controls, with Results of Sensitivity to Penicillin and Streptomycin*

Source	Cases of Infantile Diarrhoea and Vomiting	Controls		
		In-patient	Out-patient	Total
Total Nos. of cases ..	119	78	44	122
Staph. pyogenes isolated	53 (44·5%)	41 (52·5%)	15 (34%)	56 (46%)
Penicillin-resistant ..	15 (28·3%)	13 (31·9%)	9 (60%)	22 (43·9%)
Streptomycin-resistant	2	2	0	2

TABLE II.—*Incidence of Phage Types in Strains of Staph. pyogenes Isolated from Cases of Infantile Diarrhoea and Controls*

Source of *Staph. pyogenes*	Numbers of Phage Types											
	Not Typable	6	6/47	31	47/53	47/54	47	47B	52	52A	53	54
Cases of diarrhoea and vomiting (53 strains)	11	1	5	1	2	4	19	2	2	3	2	1
Controls (56 strains)	9	2	5	3	1	2	19	1	6	0	4	4

Discussion

The presence of *Staph. pyogenes* in the stools of 44.5% of infants suffering from diarrhoea and vomiting and in 46% of controls who either were not suffering from diarrhoea and vomiting or were normal, the close similarity of phage-type distribution in the two groups, and the close correlation of sensitivity to streptomycin and penicillin do not seem to indicate that the organism bears any causal relationship to infantile diarrhoea and vomiting.

The use of a highly selective medium for the isolation of *Staph. pyogenes* from the stools explains the high incidence of the organism, as on only four occasions was *Staph. pyogenes* isolated direct on blood agar—twice in cases and twice in controls.

There were 13 deaths recorded in children examined bacteriologically; in four of these *Staph. pyogenes* was isolated, but then only as a result of using the selective salt–meat medium. It should be mentioned that the number of staphylococci in the original inoculum was not known. In cases and controls in which *Staph. pyogenes* was present there may have been fewer than 10 organisms, because, as Maitland and Martyn have shown, the salt–meat medium will detect small numbers of staphylococci when mixed with large numbers of other bacteria. The failure to isolate staphylococci direct on blood agar, except in four instances, suggests that the number of staphylococci present in the stools is very low. The failure of cases to respond to streptomycin therapy (Holzel, Martyn, and Apter, 1949) does not suggest that an organism nearly always found to be sensitive to the antibiotic *in vitro* bears any causal relationship to the disease. None of the cases in this investigation were found to have either blood or pus in the stools as did many of the cases recorded by Draper and Brown (1946): whether they were dealing with the same clinical condition is a matter of conjecture.

If consideration is given to all the data available there seems to be no evidence that *Staph. pyogenes* bears any direct causal relationship to infantile diarrhoea and vomiting.

Summary

A bacteriological investigation of the incidence of *Staph. pyogenes* was carried out in cases of infantile diarrhoea and vomiting and in infants not suffering from any gastro-intestinal abnormality.

Staph. pyogenes was isolated from 44.5% of the stools of 119 cases of diarrhoea and vomiting and from 46% of controls. Only four streptomycin-resistant strains were encountered in 109 strains of *Staph. pyogenes* tested.

Bacteriophage types were distributed evenly in the two groups. Type 47 predominated, being found in 35% of the total number of strains tested. A food-poisoning type (6/47) was found five times in each of the two groups. The relationship of *Staph. pyogenes* to infantile diarrhoea and vomiting is discussed, and the general conclusion is drawn that this organism bears no relationship to the disease.

I wish to thank Professor Gaisford for his interest and advice, and to acknowledge my thanks to Professor Maitland for his help and criticism, to Dr. R. E. O. Williams and Miss J. Rippon, of the Central Public Health Laboratory, for sending me staphylococcal phages and propagating strains, and to Mr. K. Boulter for technical assistance.

MORTALITY AND SURVIVAL RATES IN MALES WITH SILICOSIS OR SILICO-TUBERCULOSIS

BY

H. MIDGLEY TURNER, M.D., M.R.C.P., D.P.H.

Chest Physician, Sheffield Regional Hospital Board; Lecturer in Tuberculosis, Sheffield University

AND

W. J. MARTIN, D.Sc., Ph.D.

From the Medical Research Council's Statistical Research Unit, London School of Hygiene and Tropical Medicine

Whilst the literature on silicosis and silico-tuberculosis is voluminous, there are few published data on the expectation of life in these two conditions. So far as silico-tuberculosis is concerned, as the prognosis is obviously dominated by the tuberculous element its assessment is not unduly difficult to the experienced chest physician. The necessity for data is much greater in silicosis without tuberculosis, as the question of expectation of life may be raised in connexion either with life insurance or with compensation, but most physicians see too few cases to establish criteria. The data upon which this paper is based have been accumulated by one of us (H.M.T.) in Sheffield during the last 19 years; the statistical analysis is the work of the co-author (W.J.M.).

Sheffield is traditionally the home of the grinder, but it is perhaps not so well known that a number of other trades in Sheffield also carry an occupational hazard of silicosis. These trades are sand- and shot-blasting, fettling steel, steel-dressing, ganister mining and quarrying, ganister-crushing, silica-brick making, building, repairing, and scaling furnaces lined with silica bricks, stone-masonry and stone-dressing, and finally coal-mining. Records have been accumulated of 857 men in whom some degree of silicosis or of silico-tuberculosis has been diagnosed. Of these 43 had no opportunity of reaching the age of 40 years, and have been excluded. The series therefore consists of 814 men with silicosis or silico-tuberculosis each of whom reached the age of 40 years and had the opportunity of reaching the age of 41 or more.

The reasons for the selection of 40 as the commencing age in the series are as follows. Silicosis is a condition which develops gradually as a result of an occupational hazard over a period of years. The proportion of cases in which it is possible to diagnose silicosis with certainty below the age of 40 varies in different processes, but is comparatively small. After the age of 40 this proportion increases fairly rapidly. Nevertheless, even before the lung changes have progressed to diagnostic level on a radiograph, they have from a pathological point of view been initiated and such risks to health as may be associated with silicosis have started to operate. With the same line of argument, it appears logical to credit a case in which silicosis was first diagnosed at the age, say, of 52 with survival from age 40 to age 52, because there can be no doubt that the silicotic hazard has existed continuously since the age of 40. It is necessary to have some standard with which comparison of the survival rates in silicosis and silico-tuberculosis can be made. For this purpose the data in the English Life Table No. 10 (Registrar-General, 1931) have been used. From the "lx" column a percentage survival rate for ages over 40 has been calculated. This represents the survival rates for males in England and Wales starting at age 40.

Survival rates at ages over 40 for silicosis and silico-tuberculosis together with the control survival rates are given in Table I and expressed graphically in the Chart.

TABLE I.—*The Number of Survivors at Each Age Expressed as a Percentage of the Number at Age 40*

Age	Silico-tuberculosis (466 Men)	Silicosis (348 Men)	English Life Table No. 10 (1930–2)

70	5·7	18·0	53 6
71	4·5	16·3	50·3

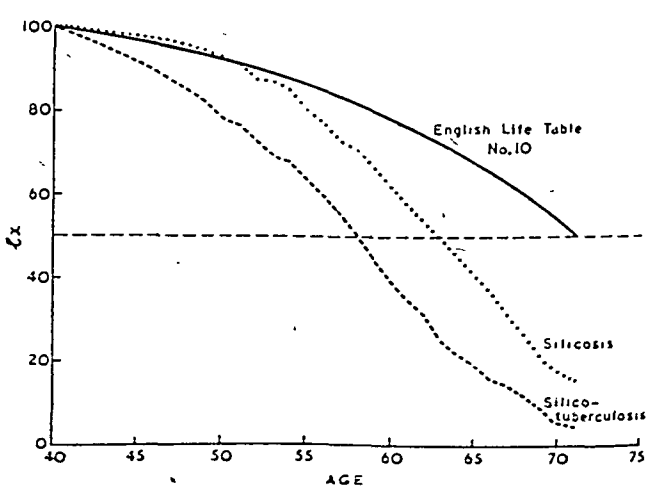

Chart showing percentage of survivors from age 40.

Before considering these findings it is necessary to give further information with regard to the series upon which the analysis is based. The 814 cases divide into 466 in which silicosis accompanied by tuberculosis was diagnosed and 348 in which silicosis without tuberculosis was diagnosed (referred to below as "pure silicosis") All cases in which a diagnosis of tuberculosis was made at any time are in the group of silico-tuberculosis. It is interesting to note, however, that the group of pure silicosis cases was a relatively stable group, and only 23 cases were first diagnosed as pure silicosis and later developed tuberculosis. In this series, therefore, the chances of a case originally diagnosed as pure silicosis later developing tuberculosis were 6 in 100. The 23 cases included a man diagnosed as a case of heavy silicosis at the age of 69 who developed acute tuberculosis one year later, and a man aged 62 who developed tuberculosis at the age of 63. The other 21 cases ranged in age from 33 to 57 (average 46 years) when silicosis was first diagnosed. The average age at which tuberculosis was diagnosed in these 21 cases was 54 years.

Of the 814 cases in the whole series 610 (75%) have been followed till death occurred; the remainder, with the exception of 15 cases which "left the area" or were "lost sight of" at various ages, are still alive. These 15 cases drop out of the survival table at the age at which they were last known to be alive. The distribution of the series between various occupations is given in Table II. It will

TABLE II—*Distribution of the Cases Between Various Occupations*

Occupation	Silico-tuberculosis		Pure Silicosis		Totals
	Alive	Dead	Alive	Dead	
Grinders	49	280	52	140	521
Fettlers and steel-dressers	9	32	19	24	84
Coal-miners	8	15	24	16	63
Masons and stone-dressers		21	1	20	42
Ganister-workers, quarry, mine, crushers, etc.	3	14	11	11	39
Sand- and shot-blasters	3	12	8	5	28
Furnace builders and repairers	6	5	4	4	19
Miscellaneous	4	5	3	6	18
Totals	82	384	122	226	814

be noticed that the ratio of silico-tuberculosis to pure silicosis varies in different trades. Thus of 521 grinders 329 (63%) had silico-tuberculosis, of 84 fettlers and steel-dressers 41 (49%) had silico-tuberculosis, whilst of 63 coal-miners only 23 (37%) had silico-tuberculosis. The appreciably lower proportion of silico-tuberculosis in coal-miners is in line with the experience of other workers. Fletcher (1948) discusses at some length the relation of tuberculosis to the pneumoconiosis of coal-miners, and sums up by stating that clinically tuberculosis appears as an infrequent but often serious complication of the disease.

Clinical experience in Sheffield supports the view that the prognosis so far as tuberculosis is concerned in the silico-tuberculosis of coal-miners is better than the prognosis of comparable cases in grinders. Gardner and others (1930) cited experimental evidence in favour of the theory that the dust from coal may exercise a favourably modifying effect on the development of tuberculosis. Reference has been made elsewhere (Turner, 1939) to the fact that, quite apart from the question of silicosis, the incidence of sputum-positive pulmonary tuberculosis among coal-miners in the Sheffield area is not high, and that, moreover, it shows an absence of the middle-age peak in the age-incidence curve which is a characteristic feature in the age-incidence curve for occupations unfavourable with regard to tuberculosis. Cummins (1935) suggested that coal dust in a miner's lung acts as an adsorbent of tuberculin and in so doing reduced the toxicity of any lesions which may occur. This theory and the work of Cummins and Weatherall (1931) upon which it is based must be accorded considerable weight.

The very high proportion of grinders who develop tuberculosis with silicosis has in the past been attributed to the harmful effect of silica together with the bad working conditions that have prevailed in the industry. It is, however, well to bear in mind that grinders and sand- and shot-blasters are abrading steel and may well also inhale fine particles of the metal. Tuberculosis is a common complication of the sidero-silicosis found in haematite miners. Stewart and Faulds (1934) gave details of post-mortem findings in 15 haematite miners, and in 11 of these the lungs showed evidence of tuberculosis accompanying the sidero-silicosis. It is possible, therefore, that the presence of iron in the lungs may exercise an unfavourable effect on local tissue resistance to tuberculosis.

Discussion of Findings

As would be expected, the survival curve for silico-tuberculosis shows the greater deviation from the control survival rates, and this deviation begins in the first year of risk. Tuberculosis with or without the mention of silicosis is the cause of death in the majority (313 of 384 deaths in this group were due to tuberculosis). At the Johannesburg Conference (Gardner and others, 1930) the question was put, "What is the prognosis in a case of silicosis with tuberculosis?" The agreed answer was, "This is always serious; it is worse (1) when the tuberculous infection occurs at the outset of the silicosis, (2) in younger than in older subjects, (3) than in cases of tuberculosis alone." Clinical experience in Sheffield endorses this answer, with a reservation on its second part. When tuberculosis either first manifests itself or recrudesces in later life it is often of an acute type with a rapid downhill course.

One handicap in the treatment of silico-tuberculosis is that collapse therapy is rarely either indicated or helpful. There are several reasons for this. The majority of the patients are in their fifth or sixth decade, and there is often difficulty in judging the contralateral lung both with regard to its functional capacity and also to the presence of active tuberculous lesions. It is probably the almost invariable reduction in cardio-respiratory capacity, due partly to concomitant emphysema, which is the main contraindication and which is responsible for disappointments when collapse therapy is tried. In favourable circumstances with conservative treatment, particularly in the middle-age group, there is a tendency for the disease to assume the productive form, and such cases may survive for many years without ever achieving complete quiescence, but with only moderate disability. In a small proportion complete arrest of the tuberculous disease is obtained, but even so life is usually shortened because of damage to the cardio-respiratory function. In view of the generally poor prognosis in cases of silico-tuberculosis where the disease is in the exudative phase, and the general lack of application of collapse therapy, experiments with streptomycin would be justified. One such case can be quoted.

A steel-dresser was first seen in 1931, at the age of 39, when he had slight silicosis. He continued at his trade and in 1943 was seen again, and an *x*-ray film showed moderate silicosis. In 1946 the position remained unchanged. In November, 1948, at the age of 57, he had a febrile illness, diagnosed as a bronchopneumonia localized to the left lower zone. As his recovery was slow he was referred to the chest clinic, and proved to have a localized exudative tuberculous lesion in the left lower

lobe, with tubercle bacilli in the sputum; there was moderate silicosis of both lungs. He was admitted to a sanatorium and given 1 g. of streptomycin daily for 60 days. Within three weeks the sputum disappeared and a radiograph showed diminution of the mottling in the left lower lobe, suggesting that the exudative reaction had ceased and that the absorptive and productive phase had started. Six months after the beginning of treatment he was able to return home, with the tuberculous process apparently quiescent, general condition excellent, and B.S.R. 6 mm. in the hour.

Turning to pure silicosis, it will be noticed that the survival rates up to the age of 51 years are almost identical with the control rates. Thereafter the silicosis group shows a definite adverse deviation which increases year by year, until by the age of 65 the survival rate is 27% below the control and only 20% above that for the silico-tuberculosis group. These findings indicate that pure silicosis is associated with a definite decrease in expectation of life as compared with males in the community at large. Table III shows that, excluding the 313 deaths due to pulmonary tuberculosis, 209 (70%) of the remaining 297 deaths were due to respiratory conditions. In clinical experience, also, the effects of silicosis and its frequently concomitant emphysema and bronchitis on the cardio-respiratory function begin to become more apparent with each passing year after the age of 50. Shortness of breath on exertion causes some limitation of activities in the majority of silicotics by the age of 55, and in some this reduction of cardio-respiratory function constitutes the salient feature of the clinical picture. How much of this disability is due to emphysema and loss of elasticity of the lungs and how much is due to changes in the pulmonary circulation and the right heart is a matter meriting further study. There is, however, little doubt that the resistance of elderly men with silicosis to respiratory infections is less than could reasonably be expected. When pneumonia occurs in men with silicosis it is serious, and radiological residua are common in survivors. These residual shadows are probably due to persisting lobular or segmental collapse.

TABLE III.—*Cause of Death in 610 Cases*

Cause of Death	Grinders	Fettlers and Steel-dressers	Coal-miners	Other Trades	Totals

Cause unknown	7				7
Totals	420	56	31	103	610

One other cause of death which deserves further reference is cancer of the lung. 32 (11%) of 297 deaths from causes other than tuberculosis were due to cancer of the lung, and there was one death from cancer of the larynx. Of the deaths from cancer of the lung 19 occurred in grinders, which suggests a heavy incidence in this group of workers when account is taken of the toll exacted by tuberculosis before the cancer age period. Although no statistical significance attaches to such small figures, their trend supports findings in a previous investigation into the cancer mortality in certain Sheffield trades (Turner and Grace, 1938). This significantly excessive mortality from cancer of the respiratory tract was found in engineers, foundry workers, and grinders, but in none of the other occupational groups investigated. Kennaway and Kennaway (1936) discuss the question whether there is any association between silicosis and cancer of the lung. They show that metal-grinders have a high rate for cancer of the lung, while stone-masons show only a slightly increased rate, and conclude that the factors which lead to silicosis are not active in producing cancer of the lung or larynx. It may possibly be that the inhalation of metal dust in the grinding process is of more importance in this connexion than the inhalation of silica. Brockbank (1932), in a survey of primary intrathoracic cancer, gave full occupational details for 52 male cases, and 13 of these had worked with iron and steel.

It has been shown that expectation of life is reduced in both silico-tuberculosis and pure silicosis, and it may be helpful to express this reduction quantitatively. If the expected age at death in each group is taken to be the age at which the living members equal those who have died, or, in other words, the age at which the chances of being alive or dead are equal, it will be found that under the conditions of this investigation the expected age at death for silico-tuberculosis is 58, for pure silicosis 63, and for males in the general population 71 years. Thus from age 40 there is a reduction in expectation of life of 13 years for the silico-tuberculosis group and of 8 years for the pure-silicosis group.

Summary

Survival rates at ages over 40 in a series of 814 men with silicosis or silico-tuberculosis have been calculated.

It has been shown that survival rates for males with silico-tuberculosis compare very unfavourably at all ages over 40 with the rates for males with pure silicosis or with the control rates for males in the general population. There is a reduction of 13 years in the expectation of life at age 40 for the group with silico-tuberculosis.

Up to age 51 the survival rates for males with pure silicosis are similar to those of males in the general population. After the age of 51 there is an adverse deviation in survival rates for the group with pure silicosis. This results in a decrease in expectation of life of eight years from age 40, as compared with the expectation of life of males in the general community. It is suggested that this is due to the effects of silicosis on cardio-respiratory function and on the capacity to resist respiratory infections.

PARAFFIN PNEUMONIA

BY

MICHAEL GELFAND, M.D., M.R.C.P.
Physician, Salisbury Native Hospital, Southern Rhodesia

It is not uncommon for cases of paraffin (kerosene) poisoning to be admitted to the children's ward of the Salisbury Native Hospital. Since paraffin has many interesting effects, particularly on the respiratory tract, I consider it of general interest to describe the clinical picture that such ingestion might produce. Further recognition of the disorder may easily be overlooked, although doctors practising amongst Africans may be well aware of the consequences of this accident.

The condition is seen particularly among infants living in native compounds, where the paraffin lamp is used for lighting. When the lamp is filled, the remaining paraffin is sometimes not emptied back into the bottle but left in a mug. It is not difficult to appreciate the danger of such a practice, as the crawling infant may easily snatch the container and consume its contents. The child coughs and cries; the mother is alarmed and rushes him to the hospital, where, as a rule, after the stomach is washed out he is admitted for the night.

The infant's condition is usually satisfactory, though there will be some rise in temperature, with the presence of a cough. In most cases the child is not very ill; but certain physical signs, such as an impairment of the air entry and inspiratory crepitations in the affected parts of the lungs, may be evident. Dullness and tubular breath sounds will not be present unless the patch is large. In most cases the lesions are found in one or both regions of the lower lobes of the lungs.

A radiograph taken at this stage of the illness, about 24 to 36 hours after the onset, generally reveals areas of "cotton-wool" opacities of small irregular size. In the more extensive cases, however, the lesions are lobar or lobular in appearance. They may be unilateral or bilateral.

The fever usually lasts a few days, the temperature then gradually returning to normal. At the height of the fever the respiratory rate may be increased as well as the pulse. The temperature generally varies from 100 to 103° F. (37.8–39.4° C.). So far I have not encountered any fatal cases or sequelae; all the patients made an uninterrupted recovery.

The differential diagnosis of paraffin poisoning is that of any acute respiratory affection, such as acute bronchitis or pneumonia. Malaria and acute febrile states may have to be considered also.

Illustrative Cases

Case 1.—A native male infant aged about 1 year was admitted on January 1, 1949, with a history of having drunk some paraffin the previous night. The mother did not know what amount had been taken, but believed it was not much. The child coughed and attempted to vomit. He was a well-covered child. The temperature was 99.7° F. (37.6° C.); the next evening it had risen to 101° F. (38.3° C.), after which it gradually subsided, reaching normal a few days later. On admission the pulse rate was 140 and the respiratory rate 36 a minute, dropping to 130 and 24 respectively after four days. On examination of the chest tubular breathing was audible in the left base, moist crepitations over the same area being heard later. The rest of the physical examination was negative. The white cell count was 13,100, with 60% neutrophils, 33% lymphocytes, and 7% monocytes. No malaria parasites were found in smears prepared from the peripheral circulation. On admission the stomach was washed out, when the smell of paraffin was detected. No special treatment, such as the use of penicillin or sulphonamides, was given. A radiograph taken on January 26 showed a large area of homogeneous consolidation at the left base, with a more extensive zone of mottled densities in the corresponding area of the right lung.

Case 2.—A native female infant aged about 1 year was admitted on April 25, 1948, with a history of having consumed 2 oz. (57 ml.) of paraffin that day. On admission the temperature was 102° F. (38.9° C.) and the child was slightly dyspnoeic. The temperature varied from 100–102° F. (37.8–38.9° C.) for the next three days, after which it gradually subsided to normal. Physical examination revealed inspiratory crepitations, mostly at the right base but with a few on the left. The mouth and throat were normal, the abdomen was slightly protuberant, and no enlargement of the spleen or liver was detected. The heart was normal, and no abnormal changes were noted in the nervous system. The urine was clear of albumin and sugar. Peripheral blood smears were negative. A radiograph of the chest taken on April 27 showed a soft area of consolidation in the lower zone of the left lung. On April 29 the child was discharged as fully recovered.

Case 3.—A native male infant aged about 15 months was admitted on December 6, 1948, with a history of having accidentally swallowed 2 oz. (57 ml.) of paraffin, after which he had vomited three times. On admission he was coughing, and paraffin could be smelt in the breath. The temperature was 103° F. (39.4° C.). He was given a gastric lavage. Examination of the chest revealed crepitations at the left base with bronchial breathing. Nothing else of note was found in the lungs. The mouth, throat, heart, abdomen, and central nervous system all appeared normal. No malaria parasites were found in smears taken of the peripheral blood. The total white cell count was 15,600 (43% neutrophils, 49% lymphocytes, 5% monocytes, and 3% eosinophils). The patient made a rapid recovery, the temperature returning to normal within three days.

Case 4.—A native female infant aged about 1 year was admitted on February 16, 1949, with a history of having swallowed paraffin a few hours previously. According to her mother, the amount consumed was about 1 oz. (28 ml.). On admission her temperature was 104° F. (40° C.), pulse 130, and respirations 30. She coughed, but no physical signs were observed in the lungs. A gastric lavage was given soon after admission. A radiograph taken the following day revealed a patchy consolidation in the lower zone of the left lung. The child was given 20,000 units of penicillin three-hourly by intravenous injection and 0.25 g. of sulphadiazine four-hourly by mouth. The temperature subsided rapidly, and two days after admission she had fully recovered and was discharged.

Case 5.—A native female infant aged about 15 months was admitted from the Location Dispensary by Dr. L. Stern, having swallowed paraffin on the afternoon of the previous day. She became very restless and later feverish. The next morning she vomited and developed a cough and some diarrhoea. Later, on admission (February 11, 1949), the temperature was 102° F. (38.9° C.) and she was coughing. The mouth and throat were healthy and the abdomen normal. The urine was free of sugar and albumin. The central nervous system was normal. The lungs did not reveal any gross changes on physical examination, but a radiograph showed a well-marked lobar consolidation of the upper zone of the right lung. The stomach was not washed out. The fever gradually subsided to normal after about six days and the patient was discharged.

Discussion

The literature, especially from America, contains a number of references to paraffin poisoning and pneumonia. Barbour (1926) reported four cases, one of which was fatal. Another fatal case was recorded by Higgins (1933), who suggests that the serious sequelae following the ingestion of paraffin are due to pulmonary involvement from aspiration of the liquid into the lungs. Waring (1933) emphasized the frequency of this type of poisoning. Some of his experiments on dogs tended to show that the pulmonary

involvement was due to aspiration of the paraffin direct or by regurgitation from the stomach into the lungs. Clinically, 9 (39%) out of 23 patients developed pulmonary changes varying from mild bronchitis to a fatal pneumonia.

Nunn and Martin (1934) recorded their findings in a series of 65 cases. These showed that 43% of the cases had aspirated some of the paraffin into the lungs. There was a mortality of 9%, all the fatal cases showing evidence of a pneumonitis. Fatalities occurred within the first 18 hours after ingestion. These authors therefore concluded that the prognosis was directly proportional to the amount of hydrocarbon entering the lungs. Their conclusion that all fatalities occurred within 18 hours after the ingestion of paraffin was corroborated by Farabaugh (1936) when he reviewed the various reports on cases of paraffin poisoning found in medical literature.

From experimental work on rabbits, Lesser, Weens, and McKey (1943) concluded that the pulmonary manifestations in these animals were due to aspiration of paraffin into the lungs rather than to its absorption from the gastro-intestinal tract. No changes were noted in the lungs of rabbits given varying amounts of paraffin by stomach tube. However, when the paraffin was administered by means of a tracheal catheter, pulmonary oedema and, later, confluent pneumonia were seen. Of a series of 22 cases of paraffin poisoning studied radiographically, 17 (77%) showed pulmonary changes.

Similar experiments on the action of paraffin on the lungs were reported by Deichmann *et al.* (1944). After administering it to rabbits by mouth or intraperitoneally they concluded that the vascular damage through absorption in the blood stream accounted for changes in the bronchi, and that the pathological lung changes were of the same character whether the paraffin was given by stomach tube or by intraperitoneal injection. In view of lung manifestations due to paraffin carried via the blood stream as well as from direct contact resulting from aspiration, these investigators stressed the necessity for early and efficient removal of all traces of the oil from the gastro-intestinal tract in the emergency treatment. They also showed that the percentage of deaths from the same dose of paraffin varied from *nil* with highly purified paraffin to as much as 60 with less-purified products.

About the same time Scott (1944) reported what he considered to be the first case in the literature of pneumonia, pneumothorax, and subcutaneous emphysema complicating paraffin poisoning. A similar case was recorded by Lavenstein in 1945.

Steiner (1947) paid particular attention to the clinical picture. He claims that there is an acute intoxication with evidence of cerebral depression, particularly of the vagus and respiratory centres. In most cases recovery takes place in a few days. Many who ingest paraffin develop changes in the lungs, detectable clinically or radiographically. These changes vary from slight infiltration " to more serious complications." Steiner classifies the cases into three groups on the basis of severity and complications: (1) acute toxicity and depression of the central nervous system, with minimal pulmonary changes followed by rapid recovery; (2) severe pneumonia and hyperpyrexia, with prolonged recovery; (3) severe pneumonia, with evidence of degenerative changes in the myocardium, liver, kidneys, and gastro-intestinal tract.

According to Steiner, the central nervous system of infants is sensitive to paraffin. Absorption from the stomach is rapid and likely to produce symptoms within an hour after an accident. These include a rapid and feeble pulse, shallow respirations, cyanosis, and drowsiness, with occasional muscular twitchings. Most infants soon recover from these effects. The lungs, however, are often involved (Group 1). In Group 2 stupor or coma with high fever and more marked changes in the lungs (confluent pneumonia) are seen. In Group 3 the degenerative effects of absorbed paraffin on the liver, spleen, kidneys, and myocardium are superimposed on the toxicity and pneumonia. He describes a case with auricular fibrillation and flutter.

Steiner discusses the two reasons given for the production of the various syndromes—absorption via the blood stream and/or aspiration direct into the bronchi. Clinically, it appears that absorption of paraffin from the stomach has enough pathological potentiality to warrant its prompt removal by gastric lavage. Yet, while such removal has been advocated in the emergency treatment, the development of gastric hyperaemia and occasional multiple erosions of the gastric mucosa necessitate the exercise of caution during this procedure. In evaluating the outlook Steiner stresses the following: (1) age—infants are more susceptible than adults; (2) amount ingested; (3) the extent of vomiting and aspiration; and (4) the nature and rapidity of the emergency treatment.

Clinically, it is clearly difficult to state whether the pneumonic changes are due to aspiration of the liquid into the lungs in the first instance or to absorption of the paraffin from the stomach and its eventual settlement in the lungs. In most cases the radiograph reveals basal changes, thus favouring ingestion. It will be noted that in Case 5 of the present series the upper lobe of the right lung only was involved. This might be considered to favour gastric absorption rather than aspiration direct into the lungs.

Steiner claims that the central nervous system of the infant is particularly sensitive to paraffin, but in no case that I have yet seen has there been any undue central nervous depression.

Summary

Cases of paraffin pneumonia in Southern Rhodesia are reported and the clinical features described.

The prognosis, as a rule, is good, although fatal cases are on record in the literature.

In view of the complications of paraffin poisoni[illegible]14 [illegible]ng it is advisable to admit all cases to the ward for observat[illegible]ted ion.

My thanks are due to Dr. R. M. Morris, Secret[illegible]es v[illegible] ag[illegible]ary for Health, Southern Rhodesia, for his permission to publish this [illegible]ith [illegible] paper.

A new Health Sciences Building at the University of Washington was formally opened on October 9. It houses the university's schools of medicine, dentistry, and nursing. A college of pharmacy will be built later. The main auditorium, seating 600 people, is wired for television, and when the equipment is complete operations being performed in other parts of the building will be televised. Dr. Edward L. Turner is dean of the medical division.

SUCCESSFUL TREATMENT OF TWO CASES OF GANGRENOUS INTUSSUSCEPTION IN CHILDHOOD

BY

D. J. CONWAY, M.B., D.C.H.

AND

R. L. G. DAWSON, F.R.C.S.

From University College Hospital, London

Early surgical correction of an acute intestinal intussusception in childhood usually results in a satisfactory recovery, but when gangrene of the constricted bowel has occurred the mortality rate is very high. Only three recoveries were reported by Ladd and Gross (1941) in 18 cases in which a primary anastomosis was carried out to deal with this complication. A Mikulicz double enterostomy operation produced only seven recoveries in 25 cases. Similar experiences have been recorded by Nyborg (1943) and by Wakeley and Atkinson (1938).

The onset of an intussusception in childhood is usually marked by sharp bouts of severe abdominal colic, though sometimes this symptom may be difficult to recognize or quite indefinite. Vomiting on one or more occasions occurs in the first 24 hours. Anorexia is often pronounced, and some pyrexia is present in the majority of cases. The motions are often looser than usual, but in about 50% no blood is passed in the first 24 hours. Though the "red-currant jelly" stool is characteristic, only streaks of blood may be passed or the motions may merely appear dark from altered blood, and the condition should not be overlooked in such cases. The shocked state of the child between paroxysms of colic is also an important point, and it is easier to palpate the abdomen at this time. If an abdominal mass is present it is prominent during peristalsis, though tightening of the abdominal wall and screaming may interfere with examination. Rarely, constriction at the neck of the intussusception is not severe enough to interfere with the vascular supply of the invaginated gut or to cause much intestinal obstruction. In such a case the history is of recurrent bouts of peri-umbilical pain for days or weeks without vomiting or the passage of blood per rectum. In the following two cases absence of a typical clinical picture resulted in a serious delay in diagnosis and admission to hospital.

Case 1

A boy of 22 months was admitted because of vomiting, restlessness, and anorexia since a brief attack of diarrhoea five days before. One convulsion occurred the day before admission. He had been treated for gastro-enteritis with sulphaguanidine, as his mother had suffered from a bout of diarrhoea at the same time. There was now no abdominal colic and the stools were normal. On examination he was listless, hypotonic, and dehydrated, but the skin colour was good. He was distended and resented abdominal palpation, but no localized tenderness or mass was detected. The urine was normal and contained chlorides. Other systems were normal. His temperature was *98.4° F. (36.9° C.), pulse 140, and respirations 40.* He was given an intravenous infusion of half-strength Hartmann's solution with 5% glucose. Twelve hours later he passed a tarry motion for the first time, and the distended abdomen then showed peristaltic waves. A barium enema confirmed the presence of an intussusception in the right half of the transverse colon.

Operation under general anaesthesia was performed by Mr. Gardham. On opening the abdomen by a right paramedian incision greatly distended intestine escaped from the wound. Complete reduction of the intussusception was not possible, and there remained a length of about 2 in. (5 cm.) of ileum situated some 6 in. (15 cm.) from the ileo-caecal valve in which there was an irreducible intussusception. Owing to the peritoneum splitting over a distended ileum, and in order to return the small intestine to the abdomen, a catheter was inserted into the ileum and the contents aspirated. The gangrenous intussusception was resected and a double-barrelled ileostomy was formed at the lower end of the incision.

During the operation and for 48 hours afterwards gastric suction was applied. For the first 12 hours it was used continuously, and then during alternate hours. For the first six post-operative days the child had half-strength Hartmann's solution with 5% glucose intravenously, each pint alternating with a pint of half-strength plasma. A watch was kept on the plasma chlorides, and when these were reduced normal saline was infused until the level was corrected. Before oral feeding was started the daily intravenous fluid intake was 3 oz. per lb. (180 ml. per kg.) body weight; later, as the quantities of food by mouth increased, the intravenous infusion was decreased. Twenty-four hours after operation he was given hourly 1-oz. (28-ml.) feeds of water during the day, and after 48 hours small feeds of 1½ oz. (42 ml.) of half-strength reconstituted dried milk three-hourly for six feeds in the day. By the sixth post-operative day he was taking 4-oz. (114-ml.) feeds thickened with a proprietary food five times in the day. He had a pyrexia of 101° F. (38.3° C.) for the first 10 days; penicillin, 50,000 units, was therefore given eight-hourly and a course of sulphadimidine for one week.

Four days after operation the abdomen was still distended. *The ileostomy did not work well at first, becoming blocked intermittently.* The abdominal wall round the ileostomy became very excoriated and was treated by splinting the child's arms to prevent him from scratching, exposing it to the sun, and applying polyvinyl alcohol jelly buffered to *p*H7. The jelly was warmed to make it more fluid, and was applied to the skin every two or three hours during the day and night; on cooling, it set as a thin impervious layer protecting the underlying skin.

A month after the original operation the ileostomy was separated from the parietes, the distal loop of ileum closed with catgut, *and the proximal loop joined to the caecum by* an end-to-side anastomosis. An intravenous infusion of half-strength Hartmann's solution with 5% glucose was again alternated with plasma intravenously for three days; from this time the child's recovery was uneventful, and he was discharged from hospital seven weeks after admission.

Case 2

A boy of 9 months was admitted because of drowsiness and vomiting of all feeds for 24 hours. He had developed a slight cough three days before, which was improving. He had anorexia, though usually his appetite was good. The last normal stool was passed just before the onset of the vomiting. At no time was there obvious colic and he did not scream *or draw up his legs.*

The child looked ill, shocked, and pale, but was well nourished and big for his age. There was no dehydration. The pulse rate was 180 a minute and the temperature 102° F. (38.9° C.). The abdomen was soft and easily palpated without tenderness or guarding. A small ill-defined swelling was present in the left hypochondrium, extending in the line of the proximal descending colon for 2 to 3 in. (5 to 7.5 cm.). Visible peristalsis was not found, and there was no abnormality on rectal examination. Other systems were normal. Fresh *blood and mucus were passed per rectum for the first time* an hour after admission. Intussusception was diagnosed, and an intravenous drip of half-strength normal saline and 5% glucose was set up preparatory to surgical treatment.

At operation under general anaesthesia Mr. Gardham found a little free fluid in the abdomen; the intestines were not distended. The head of the intussusception was felt in the splenic region. Reduction of the mass could be effected as far as the middle of the ascending colon. Beyond this point the

bowel was gangrenous, and resection of the proximal 3 in. (7.5 cm.) of ascending colon and caecum, the appendix, and the distal 2 in. (5 cm.) of the ileum was carried out. Thrombosed veins were present in part of the mesentery removed. The ileum and remaining parts of the ascending colon were double-barrelled; they were brought out through the lower end of the incision and clamped with Pringle's clamps, these being left attached and removed after 12 hours.

The post-operative condition of this child was fair. He was put on prophylactic penicillin, 30,000 units four-hourly, and sulphadimidine, 0.5 g. four-hourly. The ileostomy began to function on the third post-operative day. Intermittent gastric suction was continued for three days, and the intravenous infusion was kept up with half-strength Hartmann's solution containing 5% glucose alternated with half-strength plasma. Normal saline was substituted whenever the plasma chlorides were reduced. After 48 hours he started ½-oz. (14-ml.) feeds of expressed breast milk three-hourly, as he had previously been in process of being weaned. The size of oral feeds was rapidly increased, so that by the fourth post-operative day he was taking eight 1½-oz. (42-ml.) feeds daily.

On the fifth post-operative day the temperature rose and the ileostomy ceased to function, vomiting recurred, and gastric suction was restarted. Next day abdominal distension was apparent, the child looked ill, and an *x*-ray film of the abdomen showed multiple fluid levels in the small intestine. A high intestinal obstruction was diagnosed.

Operation under local 2% procaine was performed by Mr. Gardham, using the right-oblique-muscle-cut approach. Distended and congested bowel was found in the region of the duodeno-jejunal junction, caused by a band which had kinked the bowel and had obstructed it without interfering with the blood supply. The distended loop was aspirated with a catheter, and a purse-string suture closed the hole. Intermittent gastric suction was continued for 48 hours after the second operation; then the child was given small feeds of breast milk, with gastric suction for an hour before each feed for the next four days. Twelve days after the first operation the intravenous drip was taken down, and on the 13th day a large haematoma was evacuated from the muscle-splitting incision. The sutures were removed and the wound allowed to granulate from the bottom. The wound area was exposed to the sun, and polyvinyl alcohol buffered gel was used to prevent the intestinal juice from digesting the skin. We found on this occasion that the buffered jelly did not completely prevent excoriation, so resort was had to a thick coating of aluminium paste about the ileostomy.

By the 22nd post-operative day the child had gained 1¼ lb. (0.68 kg.) in weight, but during the next 10 days 2½ lb. (1.13 kg.) was lost. The administration of 200 ml. of plasma by tube into the stomach showed satisfactory absorption. As there was no great amino-acid loss in the ileostomy faeces it was concluded that neither intestinal hurry nor lack of absorption of food was primarily responsible, but possibly there was a vitamin deficiency due to failure of synthesis in the isolated colon. When given aneurin, riboflavin, and nicotinamide in adult doses he began to put on weight again and his diet was supplemented by 20 g. of casein added to dried-milk feeds three times a day. On the 32nd day after operation an enterotome was applied; this was followed 18 days later by the passage of the first normal motion. After seven days an extraperitoneal closure of the ileocolostomy was carried out and the wound left open. The child now began to gain weight more rapidly, and he was discharged home on the 75th post-operative day.

Comment

Recent writers have expressed the need for both pre-operative and post-operative intravenous replacement therapy and gastric aspiration (Nyborg, 1943; Hindmarsh, Stewart, and Morrison, 1945; Morrison and Court, 1948). The type of fluid administered depends upon the state of shock and dehydration of the infant and upon the plasma chlorides. In the two cases reported plasma was given for shock and the nutritional state.

When the plasma chlorides were low, normal saline with 5% glucose was given until the chloride estimations were again satisfactory. If dehydration persisted, with normal plasma chlorides, half-strength Hartmann's solution with 5% glucose was given. An anaemia of 50% haemoglobin in one child was treated with whole-blood transfusion. Oral feeding was started 24 hours after operation, with 1 oz. (28 ml.) of water hourly, gradually increasing to 5 oz. (142 ml.) or more of breast milk or dried-milk feeds. Gastric aspiration with the Wangensteen apparatus was continued intermittently for 10 days.

Nyborg has recently recommended neostigmine to combat paralytic ileus, but we consider its use is not free from danger, and prefer nepenthe, intravenous fluid replacement, and gastric suction. Penicillin and sulphonamides should be given in prophylactic courses.

Of the recommended operative procedures, the Mikulicz double enterostomy operation seems to us to be safer than excision and primary suture, or oversewing and hoping the gangrenous part of the bowel will be passed spontaneously per rectum. The primary suture involves anastomosing an acute obstructed gut to a normal gut, while the latter does not relieve the obstruction at all. Oversewing, with a proximal ileostomy of the Witzel type, has been recommended, but in this type of operation the gangrenous infected segment is still left inside the abdomen.

The disadvantages of the Mikulicz procedure have been quoted as being wasting, excoriation of the abdominal wall, and further operative procedures for closure. The first disadvantage can be combated by giving vitamins and extra proteins, the second by polyvinyl alcohol gel or aluminium paste, and it has been noted how soon a well-formed stool comes from the ileostomy. Closure of the ileostomy starts with crushing the spur, with an enterotomy 10 days after the first operation, followed later by an extraperitoneal or intraperitoneal closure.

We believed that the surgical, biochemical, and feeding problems presented by cases such as the two described stand more chance of a successful solution when the surgeon and the paediatrician combine forces in the treatment of the child.

Summary

Two cases of gangrenous intussusception in childhood are described. Both were operated on and a Mikulicz procedure performed. With intravenous infusion and careful feeding both patients recovered.

We wish to thank Dr. B. E. Schlesinger and Mr. A. J. Gardham for their help and kind permission to publish this article.

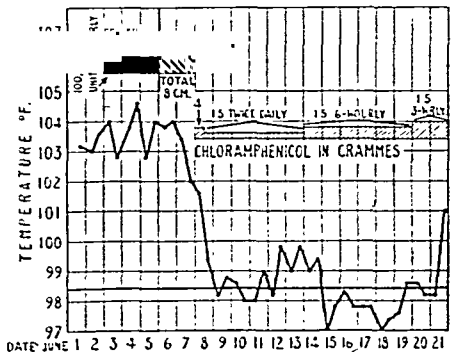
Medical Memorandum

Subacute Bacterial Endocarditis Due to Salmonella typhi-murium



In view of the rarity of subacute bacterial endocarditis due to *Salmonella typhi-murium*, the following case may be considered worthy of publication.

Case Report

A single girl, aged 19, a bottler in a mineral-water factory, was admitted to hospital on June 1. There was no previous history of illness of any kind apart from some fits in infancy. The present illness had started seven weeks before with general weakness, occasional rigors, and epistaxis, and during the week preceding admission there had been unproductive cough and bouts of diarrhoea.

On examination there were marked pallor, furred tongue, sordes on the teeth, prostration, and mental depression; temperature 103° F. (39.4° C.), pulse 112, respirations 40; throat clear; pupils and fundi normal; no neck rigidity or Kernig's sign; abdominal reflexes absent, but all deep reflexes present. A few scattered rhonchi were heard in the lungs. Examination showed no enlargement of the heart clinically, but there was a marked gallop rhythm and a blowing apical systolic murmur not conducted into the axilla and not accompanied by a thrill. The abdomen was slightly distended and tumid on palpation, but the liver and spleen were not felt. B.P. 120/80. A chest radiograph on admission was clear. Her white cells numbered 13,800 (80% polymorphs) and red cells 4,510,000 per c.mm.; Hb 81%. Blood was sent for culture and agglutination, and specimens of stool and urine for culture.

Her condition remained serious and her temperature continued without intermission as in the accompanying Chart: penicillin, 100,000 units three-hourly, was started on June 3 and

increased next day to 150,000 units three-hourly without any effect. On June 3 it was reported that there were no agglutinations to *Salm. typhi* O, *Salm. typhi* H, *Salm. paratyphi B* O, *Salm. paratyphi B* H, non-specific *Salmonella* H, or *Brucella abortus*, but on June 6 *Salm. typhi-murium* had been cultured from the Widal clot. In the meantime petechiae had appeared on the upper arms and at the root of the neck, and her general condition had deteriorated still further. The diagnosis was now apparently septicaemia due to *Salm. typhi-murium* (? subacute bacterial endocarditis), and it was decided to try to obtain a supply of chloramphenicol ("chloromycetin") from Parke, Davis and Co. in view of the results obtained in other *Salmonella* infections. Pending the arrival of the drug (over the Whitsun holidays), and in view of the patient's desperate condition, streptomycin was given six-hourly in 1-g. doses. The chloramphenicol arrived after a total of 8 g. of streptomycin had been given, and by then the patient's general condition was decidedly better, with fewer fresh petechiae and improvement in the gallop rhythm, but no marked fall in temperature. Sensitivity of the organism was demonstrated to chloramphenicol and to a greater degree to streptomycin.

Chloramphenicol 4 g. (16 capsules of 0.25 g.) was given at 10 a.m. on June 8 and was continued in 1.5-g. doses twice daily; by 10 p.m. her temperature was normal. The next day the improvement in her toxaemia was quite marked, but she developed sudden pain and swelling in the right knee with severe limitation of movement. Fundus examination showed severe toxic changes in the right macular region, and a small subhyaloid haemorrhage in the left macular region. Her diarrhoea rapidly improved and was replaced by complete constipation; but fresh petechiae continued to appear, and in view of a slight rise in temperature on June 12 and 13 it was decided to double the dose of chloramphenicol by giving 1.5 g. six-hourly. From then on her temperature did not rise above normal until she died. She continued to be extremely irritable and prostrated, however, and fresh petechiae appeared, though fewer in number; the blood pressure fell progressively to 66/50; the apical systolic murmur changed suddenly to a high-pitched musical murmur, and in spite of increasing the dosage again to 1.5 g. three-hourly she developed acute pulmonary oedema and died on June 22. At no time were specific agglutinins demonstrated against this strain of *Salm. typhi-murium*, and all specimens of stools and urine were negative on culture for that organism throughout.

Post-mortem examination showed no abnormality in the nervous system or in the abdomen, and in particular there were no lesions in the intestines, but two small white infarcts were found in the spleen. The lungs were very oedematous and there were a few small subpleural infarcts. The heart was normal in size but extremely flabby, and the myocardium was very toxic in appearance and necrotic in parts. There were two vegetations on the mitral valve, one small and one moderate in size, and apparently still active but sterile on culture. Microscopy of the vegetations showed only polymorphs present in the fibrin, and no bacteria were seen.

Comment

Systemic invasion with *Salm. typhi-murium* appears to be comparatively rare. Seligmann and Hertz (1944) report a case of cholecystitis and two cases of salpingitis; Angrist and Mollov (1946) quote Seligmann's post-mortem findings of infected dissecting aneurysm of the aorta and a case of mitral endocarditis. In general, mortality appears very high when *Salmonella* infections become invasive, and the chief help from chemotherapy is likely to be the prevention of systemic invasion by early control of the primary infection. In the present case of established endocarditis the continuing occurrence of petechiae in spite of a normal temperature, and the sudden change in quality of the cardiac murmur at the end of 12 days' intensive treatment, suggest that a much higher maintenance dosage is required at the onset of treatment than is employed in typhoid (i.e., 1.5 g. of chloramphenicol three-hourly instead of twelve-hourly), and this would possibly have to be continued for at least 28 days, on the analogy of penicillin therapy for subacute bacterial endocarditis. Fortunately the drug appears to be completely non-toxic even in such large doses.

I would like to express my thanks to Dr. W. Kwantes, of the Public Health Laboratory, Carmarthen, for his assistance with the bacteriology of this case; to Dr. A. F. S. Sladden, Director of the Beck Laboratory, Swansea General Hospital, for the pathological examinations; to Dr. Stanley White, chief medical officer to Parke, Davis and Co., for his invaluable assistance in obtaining supplies of chloramphenicol; and to Dr. Joan Taylor, of the Salmonella Reference Laboratory, for her reports on the organism.

J. DE SWIET, M.D., M.R.C.P.,
Physician, Llanelly General Hospital.

Reviews

THE PASTORAL SIDE OF MEDICINE

Rational Medicine. By John W. Todd, M.D., M.R.C.P. (Pp. 378. £1 5s.) Bristol: John Wright and Sons. 1949.

Books entitled "Rational Medicine" so often proceed to deal in irrational medicine that one is relieved to find this sensible account of some aspects of diagnosis and treatment. It begins with a critique of the value and meaning of signs and symptoms, discusses later the effects of treatment by special regimens, diet, and drugs, and describes at some length the unfortunate section of the population, referred to by William James as the tender and by the laity as the highly strung, which provides the raw material for prophets of auto-intoxication, focal sepsis, sympathetic imbalance, sexual repression, or whatever may be the current explanation of sub-average health and vitality. Dr. Todd's sceptical views on rest, constipation, psycho-analysis, and the like are in touch with current thinking, and students who read this book will be better equipped to minister to sick people than might otherwise have been the case.

"Minister" is the key word, for Dr. Todd has written a book about what has been called the pastoral side of medicine. My experience is that students find formal instruction in these matters tedious, and they are more likely to acquire the necessary skill and attitude from the example of teachers who practise than from those who preach or write. Just as dynamic psychology can only be learned by the experience of analysis and similar procedures, so the vague concept of ideas which goes by the name of psychosomatic medicine cannot be learned by the student from books, but only by the experience of working with living people under the supervision of sympathetic teachers. But if they should want a text, they will find Todd more useful than Flanders Dunbar and her school, though less profound than Clark-Kennedy.

L. J. WITTS.

AN UNORTHODOX DOCTOR

Doctor Himself. An Unorthodox Biography of Harry Roberts, M.D. By Winifred Stamp. Introduction by V. S. Pritchett and sidelights by Sidney Dark, H. M. Tomlinson, Gerald Bullett, and Lord Horder. (Pp. 165. 10s. 6d.) London: Hamish Hamilton. 1949.

It is a long time since I read a book which kept me as interested, and indeed as excited, as this. I imagine that the author enjoyed writing it as much as I did reading it. In it a very unusual kind of man has found a biographer as unconventional as himself.

by Dr. Roberts was one of three sons of a father who deter-
On the d on an income of £300 a year to make all of them
this was Harry showed his self-confidence at the age of
normal m he "wrote a book" on gardening, one of the
of the ile sions of his life, which purported to be "written
The child e of schoolmasters and others." Not particularly
discharged a scholar, he did once get a prize for an essay
t," which, the author slyly remarks, "seems to
ed him on this subject for the rest of his life."

Recent w ssible in this review to record the incredible
operative a channels into which Roberts directed his
therapy and left his medical studies at St. Mary's unfinished
Stewart, and ience master at Leek, in Staffordshire, where,
The type of fluid e made the place too hot for him by his
shock and dehydratio He defied every social convention
chlorides. In the two cases
shock and the nutritional state.

It was during this phase that he formed friendships with many of the leading socialists of the time. Some of his local friends, loath to lose him, offered to set him up in a public house. Probably Roberts would have agreed, but his wife jibbed. After a short and inglorious career on the stage he went back to St. Mary's, eking out the scanty allowance from his father by "cramming" for a correspondence college, where he became friendly with H. G. Wells. After qualifying and doing a few locums he went into general practice in Cornwall, where he did much miscellaneous authorship, always on country subjects, for he was above everything a countryman. The literary contacts he made here eventually brought him to London, where he combined journalism with general practice as a side line. There was a curious episode at this time when (though Sidney Dark, a lifelong friend, remarks that Roberts was a "born heretic") he toyed with the notion of becoming a priest in the Established Church. He went so far as to make contact with Bishop Winnington Ingram, who was prepared to accept him. But both the Bishop and Roberts realized in time that the Church was no place for a "born heretic." There followed some years of journalism, and it was not until 1904 that he found his real place in medical practice.

The story of how and why he went to Stepney is fantastic and is told with great humour and understanding. He built up there, in the most unpromising conditions, what became the largest panel practice in the country—and not only the largest but the most unconventional. In it were employed four partners, a dentist, a masseur, and two nurse-midwives. Roberts personally attended over 500 confinements in his first year. This would have more than satisfied most men, but Roberts had many other irons in the fire. For many years he wrote a "medical column" which was syndicated by a group of newspapers. He even started a weekly paper *Topics,* which had a disastrous career of three weeks.

Making money did not interest Roberts, except as a means of financing his schemes for practical social reform. He quickly became the best-known public man in the East End, largely through his work on the Stepney Board of Guardians. He was pressed to become the Labour candidate for the Division. His prospects of election seemed very promising, but, though he always regarded himself as a socialist, the book shows that he was at heart a thorough individualist and no good party man. After many quarrels with the local party he resigned his candidature, refusing to be bound by any party pledges. At one time he had written a book on *Constructive Conservatism* which brought him into contact with many of the younger Tories.

No picture of the man would be fair to him if it did not mention the way in which he discovered the small estate near Petersfield out of which he created a home and a garden. Here, in the intervals between his strenuous work in Stepney, he undoubtedly spent the happiest days of his life. It was no "week-end cottage." He and his faithful secretary, the author of this book, worked incredibly hard to make it not only a notable garden but a guest house (populated largely by "cranks"), and at one time a sanatorium for tuberculous children. The author rightly describes the inmates as "happy-go-lucky." Many notable people visited the place, where they found a congenial host. Roberts was inevitably drawn into the social and cultural life of Petersfield.

The fascination of this man is brought out in tributes by V. S. Pritchett, Sidney Dark, H. M. Tomlinson, Gerald Bullett, and Lord Horder. The last named knew Roberts personally only during the last five years of his life, but

the impression made by him is well brought out in the closing sentences of his tribute : " Havelock Ellis has said that the art of life is really the art of loving, but that we only master this art too late. It is with gratitude to Fate and with humility that I can say that in the case of Harry Roberts and myself we were just in time."

With confidence I strongly recommend this book to anyone who likes to read about a vivid personality made known by a writer who is obviously the one person who could do it.

ALFRED COX.

MALNUTRITION IN GERMANY

Das Hungerödem und andere alimentäre Mangelerkrankungen. By Professor Hans W. Bansi. (Pp. 211. No price.) Stuttgart: Ferdinand Enke. 1949.

Professor Bansi is the senior physician of the first medical division of St. George's Hospital, Hamburg, and has based his book on hunger oedema on his experiences of malnutrition during the British occupation between 1945 and 1948. The approach is mainly clinical, though there is a considerable amount of chemical and clinical pathology in the book. The author discusses the history of the condition and describes the effect of hunger oedema on the various organs of the body, on the haemopoietic system, and on the blood chemistry. There follows an account of the cause of the disease and its pathology, pathogenesis, differential diagnosis, prognosis, and treatment. The author also discusses what he calls *Mangelfettsucht* or paradoxical *Fettsucht*, an excessive fatness seen in some young women and repatriated prisoners of war which he considers was due to an endocrine dysfunction.

There is an index, though not a very detailed one, a bibliography of some five hundred references, and twelve photographs of patients suffering from hunger oedema. The book is illustrated with numerous tables and diagrams, including an interesting representation of the energy liberated by the combustion of a pound of fat in the body. This apparently provides enough energy to play 77 hours of light music but only 30 hours of Beethoven. Considering that the author's observations were made during the difficult post-war years in Germany, the number of laboratory investigations performed was remarkable. These include studies on nitrogen and calcium balance, water and creatin excretion, glucose-tolerance tests, and complete haematological investigations. Although it is difficult to contribute anything really new on the subject of malnutrition to-day, Professor Bansi has tackled the subject with Teutonic thoroughness.

F. PRESCOTT.

THE SURGEON AND THE SPASTIC CASE

Cirugia de las parálisis espásticas. By F. Bastos Mora. Preface by M. Bastos Ansart. (Pp. 151; 52 illustrations and 22 drawings. 65 cents.) Barcelona: José Janés, Publicaciones Médicas.

This account of the surgery of spastic paralysis is a successful effort to synthesize in manual form a clinical entity and a surgical problem which has taken many of us, and undoubtedly will take many others, long and painful hours to study. It is a small monograph by a collaborator of M. Bastos Ansart, on whose experience the text is mainly based.

In spite of its reduced number of pages this work includes the major features of interest in the subject, and emphasis is correctly placed on the physio-pathological factors involved. The works of Förster, Pollok, Fulton, Stoffel, and Barré are those which the author mainly follows in his study of the two principal factors contributing to the clinical picture of these patients—paresis and spasticity. The description of the part played by the sympathetic nervous system in muscular tonus is mainly based on the results of histological findings to which the Spanish school has greatly contributed, particularly Castro, Cajal, Del Rio, and Tello. A good account is given of the major signs and symptoms which form the clinical picture of the spastic case, and comment is made on the intellectual and language changes so frequently associated with this central disturbance.

The first part of the book ends with separate descriptions of the main characteristics of paralysis in the upper and lower extremities. The second part discusses the values of a number of surgical techniques which have been employed in the treatment of the condition. It is this section that is most fully based on the author's own experience. He mentions the part which may be played by efferent neurectomy (Stöffel) before excessive shortening has taken place in muscular contractures localized to one muscular group only, but he is rightly moderate in his enthusiasm for this method. Tenotomy, tendon elongation, muscular transplant, and muscular reinsertion are in general well valued, and the book ends by mentioning the most important features of surgical treatment applied to different parts of the limbs. Illustrations emphasize a number of the author's points, and a well-selected, if reduced, bibliography completes the work.

J. TRUETA.

HANDBOOK OF TROPICAL MEDICINE

An Epitome of the Laboratory Diagnosis and Treatment of Tropical Diseases. By Horace M. Shelley, M.R.C.P., D.T.M.&H. Second edition. (Pp. 147. 10s. 6d.) London: Staples Press.

There are several good textbooks on tropical medicine and more than one good synopsis, but the author of this useful brief work has confined himself to two important aspects of the subject—laboratory diagnosis and treatment. The book will not be particularly helpful to the student of tropical medicine for examination purposes, but it will be useful for quick reference by the general physician in this country, who is being made increasingly conscious of tropical infections by the many examples that he is encountering in ex-Servicemen in his practice.

The only general criticism is that the author has some weakness for sitting on fences; he too frequently uses such expressions as " may be examined " and " should be tried."

The treatment of malaria is not satisfactory : the author never faces the real problem of this disease, which is the treatment of the benign tertian infection to prevent relapses. That the complete answer has not yet been found is no excuse. The position of pamaquine in the treatment of malaria is nowhere clearly defined. Methylene blue is described as a remedy for malaria without any qualifications, and chloroquine and pentaquine are not mentioned in this chapter. The section on kala-azar is fairly satisfactory, though it is stated that solidification is the indication of a positive serum formalin reaction: the criterion is opacity, not solidification. There is no reference to the troublesome neuropathy that may follow treatment by stilbamidine, though this drug is recommended. These are not serious defects, however, and to some extent are the result of compression, with which the author has on the whole been very successful. The format is excellent and the price reasonable, but the book is not entirely free from misprints.

L. EVERARD NAPIER.

CARE OF THE TUBERCULOUS PATIENT

Tuberculosis Nursing. By Jessie G. Eyre, S.R.N. (Pp. 304; 102 illustrations. £1 1s.) London: H. K. Lewis and Co. 1949.

The author of any book on the nursing of a condition such as tuberculosis has always a difficult task in deciding how much to include and how much to leave out. Tuberculosis covers a very wide field, and a successful tuberculosis nurse must have knowledge of many subjects beyond that of attention to the patient. In the volume under review the author has carefully balanced the information on these ancillary matters with those of the actual nursing and treatment of the patient, and has thereby succeeded in producing a guide both for those who wish to undertake tuberculosis nursing as a means of gaining additional postgraduate experience and those who intend to specialize in the subject. She has also shown very clearly that tuberculosis is full of interest to the nurse, and that special training is necessary if the nursing problems are to be overcome and the patient is to receive full benefit from the treatment. The book demonstrates the important role of the nurse in the management of the case: without the co-operation of a well-trained nurse the physician can have little hope of providing his patients with efficient and beneficial treatment.

The chapters on nursing procedure are particularly good, and a useful appendix to the book contains valuable information on disinfectants, preparation of surgical equipment, and the examination of sputum. A little more care might have been exercised in the arrangement of the chapters on clinical matters, in that there is a tendency to group a number of not too closely related subjects under a caption that is really limited to a definite aspect of the disease. This may be noted in the chapters on the course and clinical picture of pulmonary tuberculosis. If future editions are published, it is hoped that information will be included on such matters as the various types of apparatus used in artificial pneumothorax treatment, epituberculosis, tuberculosis of the eye, the use of streptomycin in the treatment of tuberculous laryngitis, the jelly patch test, and the vole acid-fast bacillus vaccine. In the chapters on tuberculosis care and aftercare the functions of the regional hospital boards will have to be clarified from those of the local health authorities.

FREDERICK HEAF.

The first edition of *Pathology of the Nervous System*, by J. Henry Biggart, M.D. (foreword by Professor A. Murray Drennan; pp. 352; £1 1s.; Edinburgh: E. and S. Livingstone, 1949), published in 1936, justly enjoyed a popularity which led to its reprinting in 1940. In this second edition the general form has been maintained. It is only 17 pages longer in spite of the addition of certain sections and the rewriting of parts of the text to bring it up to date. Sections on polyarteritis nodosa and fat embolism have been added to the chapter on vascular diseases, and aneurysms of the carotid artery within the cavernous sinus now receive a note. Articles on toxoplasmosis, Boeck's sarcoidosis, acute lymphocytic chorio-meningitis, and equine encephalitis are useful additions to subsequent chapters, while the accounts of tuberculous meningitis and anterior poliomyelitis have been revised. Knowledge acquired during the war upon the effects sustained by the brain in head injuries has led to extensive revision of the appropriate chapter. Many new illustrations in half-tone appear, and a notable addition is the inclusion of ten excellent colour plates made from photomicrographs by Mr. T. Dodds, of Edinburgh University.

Specs, by "BM/TFCE" (pp. 49; 3s. 6d.; St. Albans: Cartmel; 1949) is a racily written survey which contains chapters on the National Ophthalmic Service, spectacle frames, and some elementary and not altogether accurate information on diseases of the eye.

BOOKS RECEIVED

[*Review is not precluded by notice here of books recently received*]

A Twentieth Century Physician. By the late Sir Arthur Hurst. Foreword by J. A. Ryle, M.D., F.R.C.P. (Pp. 200. 15s.) London: Edward Arnold. 1949.

Operative Surgery. By F. C. Hill, B.A., M.S., M.D. (Pp. 698. 63s.) Oxford University Press. 1949.

Is Evolution a Myth? By D. Dewar, B.A., F.Z.S., L. Merson Davies, D.Sc., F.G.S., and J. B. S. Haldane, F.R.S. (Pp. 92. 2s. 6d.) London: Watts and Paternoster Press (jointly). 1949.

Doctors East Doctors West. By E. Hume, M.D. (Pp. 278. 12s. 6d.) London: George Allen and Unwin 1949.

Recent Advances in Physiology. By W. H Newton, M.D., M.Sc. 7th ed. (Pp. 268. 21s.) London: Churchill. 1949.

Brompton Hospital Reports. Vol. 17, 1948. (Pp. 183. 10s.) London: Research Department of Brompton Hospital. 1949.

The Thyroid Hormones and their Action. By G. Mansfeld, M.D. Translated by E. Pulay, M.D. (Pp. 157. 24s.) London: Frederick Muller. 1949.

Operative Obstetrics. By J. M. Munro Kerr, F.R.C.O.G., M.D., and J. Chassar Moir, M.D., F.R.C.O.G. 5th ed. (Pp. 948. 63s.) London: Baillière, Tindall and Cox. 1949.

Society and its Criminals. By P. Reiwald. Translated and edited by T. E. James. (Pp. 315. 21s.) London: William Heinemann (Medical Books). 1949.

Ankylosing Spondylitis. Part 1 by F. Hernaman-Johnson, M.D., D.M.R.E., and Part 2 by W. A. Law, O.B.E., F.R.C.S. (Pp. 200. 25s.) London: Butterworth. 1949.

Fundamentals of Otolaryngology. By L R. Boies, M.D. (Pp. 443. 32s. 6d.) Philadelphia and London: Saunders. 1949.

The Pharmacology and Toxicology of Uranium Compounds. Edited by C. Voegtlin. Ph.D., and H. C. Hodge. Ph.D. (Two vols. Pp. 1,084. 60s.) New York, Toronto, and London: McGraw-Hill. 1949.

Female Sex Endocrinology. By C. H. Birnberg, M.D. (Pp. 128. 35s.) Philadelphia, London, and Montreal: Lippincott. 1949.

Le Diagnostic Bio-clinique en Radiologie Pulmonaire. By G. Voluter. (Pp. 452. 40 Swiss francs.) Basle and New York: Karger. 1949.

Contribución del Coeficiente Citológico a la Fisiologia y Patalogia de la Correlación Hipofisotiroidea. By E. Del Conte. (Pp. 87. No price.) Buenos Aires: Libreria y Editorial el Ateneo. 1949.

Die Heilkunde und der Ärztliche Beruf. By P. Diepgen, M.D. 3rd ed. (Pp. 304. M. 18.) Berlin: Urban and Schwarzenberg. 1949.

Das Chronische Cystische Hydrom der Dura in seinen Beziehungen zum Sog. Chronischen Traumatischen Subduralen Hämatom und zur Pachymeningitis Hämorrhagica Interna im Lichte der Relationspathologie. By A. Bannwarth. (Pp. 57. M. 9.60.) Stuttgart: Georg Thieme. 1949.

Aktuelle Probleme der Pathologie und Therapie. By H. Holthusen. (Pp. 248. M. 29.) Stuttgart: Georg Thieme. 1949.

Grundlagen der Funktionellen Urologischen Röntgendiagnostik. By W. Pfeifer. (Pp. 88. M. 9.60.) Stuttgart: Georg Thieme. 1949.

Studie zur Psychopathologie Krampfbehandelter Psychosen. By H. J. Weitbrecht. (Pp. 86. M. 8.70.) Stuttgart: Georg Thieme. 1949.

Die Dystrophie. By H. Berning. (Pp. 197. M. 18.) Stuttgart: Georg Thieme. 1949.

Anatomie und Physiologie. By J. Bücker. 6th ed. (Pp. 152. M. 15.5.) Stuttgart: Georg Thieme. 1949.

Vom Wesen der Neurose. By E. Speer. 2nd ed. (Pp. 106. M. 7.80.) Stuttgart: Georg Thieme. 1949.

HORMONES AND RHEUMATISM

In commenting on the dramatic results obtained by Hench, Kendall, Slocomb, and Polley in the treatment of rheumatoid arthritis by cortisone we referred[1] to the highly interesting series of experiments by Hans Selye and his colleagues from which they concluded five years ago[2] "that the adrenal cortex may play an important role in the pathogenesis of rheumatic and rheumatoid conditions in man." As a result of his observations Selye put forward the idea of "a general adaptation syndrome" and of "adaptation diseases." In the opening pages of this week's *Journal* Selye reviews some aspects of his work, and makes an important new contribution to the problems underlying the treatment of rheumatism with the adrenocorticotropic hormone (ACTH) and the "gluco-corticoid" hormone of the adrenal known as cortisone. He has succeeded in devising a method of producing an acute or chronic arthritis and periarthritis by the injection of formaldehyde into the tissues near a joint. Before the use of this technique experimental work on animals was held up by the fact that neither desoxycorticosterone (DCA) nor the lyophilized anterior pituitary preparation (LAP) which Selye employed produced arthritis regularly enough to permit the systematic investigation of therapeutic methods. With this difficulty overcome Selye has been able to study the influence of the pituitary-adrenocortical system on the production and prevention of experimental arthritis.

In his first series of observations a number of rats were given injections of DCA for fourteen days, after which a "formalin arthritis" was induced. In these rats and in the controls the immediate hyperaemic and oedematous response to the injection of formaldehyde was approximately the same. After a few days, however, the reaction tended to subside in the untreated control rats but not in the DCA-treated rats. The effect of cortisone and DCA, both separately and in combination, was then studied, and it was found that the joint swelling was very mild in the groups of rats receiving cortisone or cortisone and DCA, while it was pronounced in the remaining two groups which had received either DCA alone or no hormone treatment at all. From these and other similar experiments it became obvious that in both the acute and chronic phases of experimental arthritis cortisone inhibited, while DCA tended to exacerbate, the inflammatory process. In later experiments Selye found that if an injection of formaldehyde was preceded by one of ACTH the usual inflammatory reactions did not appear; while LAP, which will sometimes of itself produce an arthritic condition, seemed to increase the arthritis-producing effect of the formaldehyde. Certain other effects of cortisone and ACTH, among which may be mentioned involution of the thymus gland and other lymphatic organs, seemed also to be reversed as the result of sensitization by DCA and LAP.

One of Selye's previous findings had been that during the "alarm reaction" effects similar to those of cortisone are produced by any agent capable of causing systemic stress. In his present paper he shows that an experimentally produced alarm reaction inhibited the development of "formalin arthritis." This effect, he believes, is due to the endogenous secretion of ACTH and so of gluco-corticoids. This failure of animals subjected to severe stress to respond to the formaldehyde injections might be ascribed to their debilitated condition, but that this is not so can be judged by the fact that animals which showed no sign of weakness also failed to respond, while immediate and severe reactions to formaldehyde injections were observed in a series of adrenalectomized animals subjected to stresses which rendered them almost moribund.

It would seem therefore, if these experiments are confirmed, that the inhibition of "formalin arthritis," and probably other types as well, by cortisone, ACTH, and the alarm reaction is due to the direct effect of gluco-corticoids upon the injured tissues. The mechanism of this response is unknown, but it might be related to the well-known antihistamine action of the gluco-corticoids. It has long been assumed that histamine-like compounds are liberated from tissues at the site of injury and are concerned in the development of inflammation. Further investigation of the action of antihistamine drugs in some of the other clinical conditions which seem to be benefited by cortisone or ACTH might have interesting results.

The apparent antagonism between these two hormones and DCA and LAP is difficult to explain, particularly since the degree of adrenocortical enlargement produced in experimental animals by both series of hormones was almost exactly the same. Selye himself suggests that

[1] *British Medical Journal*, 1949, 1, 812.

[3] *New Engl. J. Med.*, 1949, 241, 529.

DCA, being a close chemical relative of cortisone, might prevent the latter from reaching its target organs. Possibly some competition mechanism is involved, similar to that between vitamins and their corresponding anti-vitamins.

It is evident from Selye's work and from other published reports that the anti-arthritic effect of cortisone and ACTH is to a large extent non-specific. Recently Thorn and his associates[3] have shown that ACTH has a curative action in gouty arthritis, and they have observed that an acute attack often occurs when treatment is discontinued. Selye has found too that when the onset of "formalin arthritis" has been inhibited by an alarm stimulus the condition may flare up in a particularly severe form after a period of latency. Such observations are bound to raise the question whether arthritis can be held in check indefinitely by continued treatment with cortisone or ACTH.

TUBERCULOSIS AND WAR

Twice within a period of 40 years whole populations have been forced to live in conditions of abnormal stress, and on both occasions the rise in tuberculosis mortality and morbidity rates was directly related to the devastation caused by the conflict. In spite of the disruption of national life many important epidemiological investigations have been carried out, and in the Milroy Lectures, published in this and last week's *Journal*, Dr. Marc Daniels has most ably summed up the history of tuberculosis in Europe during and after the war of 1939–45. He prefaces his study of tuberculosis mortality and morbidity with the remark that "when one presents statistics of tuberculosis in Europe it is with a feeling that they are better than no information at all, but not much better." This reservation is important, particularly as it applies to morbidity figures, for in occupied countries those diagnosed as tuberculous were able to obtain extra rations and privileges. It is known that some persons employed such devices as pressing small pieces of cotton-wool soaked in "lipiodol" on to their chests immediately before being radiographed, or chewing a small pellet of bread soaked in B.C.G. vaccine just before a specimen of sputum was taken.

Mortality figures cannot be influenced by such deceptions, but when large movements of population are taking place the influence of environmental factors is hard to assess. The experience of the island of Jersey provided some information about the effect of removing from a country large numbers of persons whose racial susceptibility to tuberculosis differed from those who remained. The population of Jersey before the recent war was composed mainly of English immigrants and Jersey natives. The former came, generally speaking, from a stock that has a fairly high racial resistance to tuberculosis, while the latter were of Breton extraction and had a lower resistance to the disease. When the war started large numbers of the English left the island, and after the German invasion most of the remainder, along with many of the healthiest of the Jerseymen, were removed to labour camps on the Continent. Dr. R. N. McKinstry, medical officer of health for Jersey, has shown in his annual report for 1947 that one of the immediate effects was a very steep rise in the mortality from tuberculosis. The high rate continued until 1945, when it suddenly fell. The rise after the outbreak of hostilities and the fall at their conclusion occurred too quickly to be related to changes in living conditions. A possible explanation for the rise might be that mainly susceptible individuals were left behind; the fall could have been due to the dilution of the susceptibles by the return of the resistant English residents at the end of the war. Some development of this theory might be possible by studying what effects the mass movement of Jews in Europe has had on mortality rates, since there is evidence that the Jewish race is more resistant to tuberculosis than other races. Something more than dilution, however, is required to explain the rapid fall in tuberculosis death rates that is taking place in Europe to-day, for only a small proportion of the displaced Jews have returned to their original homes.

Dr. Daniels refers to the need for further epidemiological studies. In spite of the mass of information available many of the wartime and post-war trends in tuberculosis cannot be satisfactorily explained. It remains an open question whether the many thousands of deaths from tuberculosis which would not have occurred but for the war were due in the main to new infections or to the aggravation of disease from which the patients would ordinarily have recovered. Except in Scotland the wartime rise in tuberculosis has chiefly affected men; in fact, in some countries the rise was confined to them. Many reasons have been put forward for this; it has even been suggested that men react more severely to malnutrition than women. Another phenomenon common to most countries is that as the mortality among males has fallen, so the peak of the curve has shifted towards the older age groups; the curve of the mortality rate for women, however, has retained a sharp peak at ages 15–24. An attempt to explain this has been made by studying the tuberculosis mortality in successive generations, and it appears that the curve of the tuberculosis mortality in different age groups plotted on a generation basis shows little tendency to change through successive decades.

Perhaps the most important anti-tuberculosis measure now in use which was not available after the first world war is mass vaccination with B.C.G. It may be that the vaccination campaign during the past 10 or 15 years has been largely responsible for the downward trend of the tuberculosis mortality rates in the Scandinavian countries. But B.C.G. vaccination will not account for the sudden fall in the figures for Holland, and for Amsterdam in particular. The extreme hardships suffered by the Dutch during the last years of the war would cause the death of many patients with active disease; the consequence would be a diminution in the foci of infection (the influenza epidemic of 1918–19 removed sources of infection in the same way). This, and a rapid improvement in diet at the end of the war and the restoration to their previous high standard of the preventive tuberculosis services, are having the desired result. There was no rise during the war in the tuberculosis mortality rate in Denmark, which, as Daniels points out, enjoyed a comparatively good standard of living. In fact Professor Knud Faber has stated that there was little or no fall in the protein and fat intake during the German occupation. In addition to this the public health services suffered little disorganization during the war and remained at their peacetime level of efficiency. In both Holland and Denmark there are three to four tuberculosis beds for each death from the disease, and therefore the segregation of infectious cases is relatively easy.

In many European countries, such as Poland, Italy, and Yugoslavia, great efforts have been made to increase the number of institutional beds. Though such beds are officially designated for treatment, the community benefits greatly by the segregation of the infectious cases. The standard of nursing in some countries is low compared with that in Britain, and one nurse may be put in charge of many patients. This at least has the advantage of overcoming the shortage of nurses, and even if the supervision of treatment has to be neglected the removal of each infectious patient from his or her home does limit the spread of infection. The use of residential nurseries and open-air schools, which in this country have a comparable value to the "preventorium," for breaking the contact between the child and the infectious adult is a development that began during the war period and should be encouraged.

In the rehabilitation of the tuberculous Great Britain leads the way. There is a great need for the spread of information about suitable methods in those European countries where no schemes are in existence. Perhaps some of the travelling fellowships recommended by the World Health Organization could be used to further the study of this important aspect of tuberculosis. At Papworth and Preston Hall and in the developing "Remploy" factories there are unrivalled opportunities for observing and investigating methods of training and rehabilitating tuberculous persons.

Dr. Daniels's study demonstrates very clearly how great an asset to any country is an efficient and well-equipped tuberculosis service. In countries with a service which before the war worked hard to prevent disease, recovery from the effects of war was more rapid than in the countries which possessed only a poor or inefficient service. The tuberculosis dispensary is still the nucleus of the service, and the development of this unit is an essential feature in all reconstructive programmes. It is noteworthy that in many countries the doctor in charge of the dispensary is regarded primarily as a tuberculosis specialist, and that in France "a tuberculosis specialist," aided by a specialist social worker, is appointed to supervise all tuberculosis work in the department. Thus there seems to be no doubt about the retention of tuberculosis as a specialty and about the need for a unified service to combat the disease. The survey made by Daniels of tuberculosis schemes in Europe affords an opportunity of looking at our own with a critical eye. In the regular examination of certain groups of the population, such as students, "we are falling far behind" several countries. There seems to be little doubt that successive annual re-examination of a community is a profitable undertaking that amply rewards the labour expended. It follows that the diagnostic and preventive services must be developed so that susceptible persons are prevented from contracting the disease, and so that appropriate treatment can be offered to infected persons when the disease is in its early and curable stage. In France the improvement in the tuberculosis services is reflected in the falling death rate; this has been greater in France than in any other country in Europe. Some of this decrease may be due to the extensive use of B.C.G. during recent years, and if this is so then due credit must be given to the pioneer work that has been done in France with this.

Dr. Daniels refers to the remarkable "sense of international duty" awakened by the war. No doubt the work of the World Health Organization, including the special assistance given by the Scandinavian countries to Unicef, has had a marked effect in reducing both the incidence and the mortality of tuberculosis in devastated countries. But there is no justification for complacency because the influence of war is receding and death rates are falling. Rather the time is opportune for even more strenuous efforts. The closing words of Daniels's second lecture are worth repeating: "Given respite from mutual massacre, there is no reason why this disease which has plagued the Continent of Europe for many hundreds of years should not be almost eradicated before the century is out."

SIZE AND ACTIVITY

The importance of scale and dimensions has been more seriously considered in relation to animal design than as affecting physical performance. It has been pointed out, for example, that a mouse which had been enlarged to the size of an elephant would be unable to stand, and that an elephant which had been contracted to the size of a mouse would be handicapped in agility by an unnecessary thickness of leg: in short that the sudden alterations in size which befell Alice in Wonderland would have raised problems of an engineering kind which her mathematician creator had failed to foresee. It has been left to Professor A. V. Hill, in a recent lecture to the Royal Institution,[1] to apply arguments of the same kind to questions of athletic performance, and to show that only in the high jump and in under-water swimming does size as such offer any advantage. The underlying geometry is simple enough: that in a scale enlargement a doubling of linear dimensions is accompanied by a fourfold increase in corresponding areas, and by an eightfold increase in volume, and incidentally in weight, provided that structural materials have been kept the same. In practice so simple an expansion is impossible, whether in engineering design or in animal anatomy, and for the nearest approach it is necessary to go to the sea, where the problem of standing up is no longer significant.

Between the blue whale, the largest of the Cetacea, and the dolphin, there is a range in length of about 12 to 1, and a range in weight of more than 1,000 to 1, though in general shape and design there is a reasonably close correspondence. Both animals move in the water with unusual efficiency, cruising for long periods at 15 knots, and being capable of shorter bursts of 20 knots or over. But on the basis of weight of muscle it has been commonly argued that the whale should have the easier task.[2,3] Parry, it is true, has pointed out that muscle power cannot be expressed as a simple function of size.[4] but Hill makes the broader physiological approach and examines the scale relationship between dolphins and whales in terms of the circulation of the blood—the factor which imposes an overall limit on rate of energy output. In one such investigation he examined the aorta of the whale, and showed that its cross-section or area was in approximately scale relationship to that of man, and presumably the dolphin. At the same rate of blood flow the aorta could therefore supply a quantity of blood in proportion to surface area, not to volume or weight. To achieve the latter proportion there would have to be a 10-times faster flow and a peak difference of pressure of the order of several atmospheres. This would obviously be impossible, and the same conclusion is supported by a comparison of heart size and heart rate. As between whale and dolphin, heart size is in proportion to weight, but heart rate should be reduced by a factor of about 8, so that it must be impossible for the larger whale to generate a horse-power in proportion to its weight. This accepted, it follows that whales as well as dolphins must possess a great capacity for inducing a smooth flow of water past their bodies, and that the performance of both should make ship designers envious.

More generally, it appears that in "similar" animals of whatever kind rate of energy output—otherwise horse-power—must be in approximate proportion to surface area, and that the development of engineering power in proportion to weight is an impossible achievement if respiratory and circulatory systems increase to scale. Other and converging arguments can also be adduced. In the case of swimming, the pressure on propulsive organs would be increased beyond possibility if they were moved at the same frequency in a larger animal as in a smaller one. In the case of running, the kinetic energy put into limb movement can only be balanced by the work done by muscles on the condition that frequency of movement is reduced in proportion as limb size is increased. The larger animal will have a slower heart beat, move its limbs more slowly, but achieve the same speed, other things being equal. Because of scale complications there is no such satisfying comparison as that between dolphin and whale. The elephant, at around 20 m.p.h., is clearly handicapped by the consequences in design of its greater size. The mouse, running flat out to safety, eludes stop-watch as well as stick. But the broad picture suggests a lesser variation in speed than might otherwise be expected. The larger greyhound is but slightly faster than the smaller whippet. The speed of the hunting leopard, which is credited with 64–66 m.p.h. in a short chase and is the fastest of all animals, is not so greatly different from the 24 m.p.h. achieved by man on his two legs. At various kinds of jumping there are closer correspondences. In a running jump the horse, large kangaroo, man, and the antelope can cover 25 to 30 ft. (7.6 to 9.1 m.) in that order, with the jumping hare only 5 ft. (1.5 m.) less. With a standing start the 4-in. (10-cm.) jumping mouse is the equal of man. Among high-jump "records" a rat kangaroo the size of a rabbit has been seen to clear an 8-ft. (2.4-m.) fence; the large kangaroo, helped by its higher centre of gravity, one of 9 ft. (2.7 m.).

There is at least general support in these figures for Hill's conclusion that, irrespective of size, animals of similar form and designed with a similar factor of safety should be able to run and swim at the same speed and to jump the same height. Muscle speed, adjusted to safety as well as function, shows a wider range, and for

1 *Science To-day*, 1949, 6, 341; *Nature, Lond.*, 1949, 164, 820.
2 Gray, J., *J. exp. Biol.*, 1936, 13, 192.
3 *Nature, Lond.*, 1948, 161, 199.
4 Parry, D. A., *ibid.*, 1948, 131, 200.

this an engineering explanation can be suggested. As with an engine, reversals of movement which were over-rapid in proportion to size would break either muscles or structural components, and the kangaroo endowed with the muscles of a grasshopper would soon suffer injury. Muscle speed is adjusted to speed of living, and speed of living depends on heart rate and so on size.

SURGERY IN PULMONARY TUBERCULOSIS

The importance of surgery in the treatment of pulmonary tuberculosis is taken for granted, but 30 years ago the help of the surgeon was not even contemplated. The co-operation between chest physician and surgeon is now as close as in any branch of medicine, and the patient has greatly benefited in consequence. Two eminent authorities, H. Morriston Davies[1] and Th. Naegeli,[2] who have been pioneers in applying surgery to the treatment of pulmonary tuberculosis, have recently discussed developments in this field, and in general their views do not diverge very far.

If an artificial pneumothorax is inefficient or contra-selective the result is bad, and when there is tracheo-bronchial tuberculosis or a persistent surface or tension cavity this form of treatment may be dangerous. In such cases, however, pneumothoraces are often maintained. These contraindications are not emphasized by Naegeli. Division of adhesions is necessary in order to maintain an artificial pneumothorax in many cases, and although this will usually be done by the cautery through a thoracoscope an open operation is occasionally required. There should be no hesitation in abandoning an ineffective artificial pneumothorax in favour of a major surgical operation. Both Morriston Davies and Naegeli recommend oleothorax for a small group of patients—in fact they would use it more often than is customary in this country. They agree that the place for phrenic crush is limited and that it is of greater value for lower lobe disease than for upper; the permanent paralysis which occasionally follows may cause anxiety if a thoracoplasty is eventually performed. Pneumoperitoneum is a valuable adjunct, especially when bilateral disease is present. While these methods of treatment may heal a cavity in the basal segment of the lower lobe, cavities at its apex in the dorsal segment often remain open, and the problem of the treatment of lesions in this part of the lung remains unsolved. It is unusual for abnormalities to be discovered at routine bronchoscopies, but if intrabronchial tuberculosis is found this may have an important bearing on treatment. Naegeli does not stress this point, nor indeed is endoscopy universally recommended.

Both surgeons pay tribute to Sauerbruch, Friedrich, and other pioneers of thoracoplasty, and discuss the various techniques which are in use. Finality has not been reached. The relaxation afforded by an apicolysis or Semb strip may not be as effective as the contramediastinal collapse which follows removal of ribs and transverse processes, and sometimes of costal cartilages too. Large cavities may require preliminary Monaldi drainage. Naegeli discusses extrapleural pneumothorax and its variants at some length. This is an operation which has always been more popular on the Continent than in England, and it is scarcely mentioned by Morriston Davies. On the other hand, the latter describes insertion of an inert plastic material to maintain permanent collapse. This, the most modern form of plombage, can be used to bring about a selective collapse of any part of the lung. The operation is done in one stage; it causes little shock and no paradoxical movement, and no refills are required. Preliminary reports refer to the relative freedom from complications, and if experience confirms this an advance of some importance will have been made. Morriston Davies prefers polythene strips contained in a pack to lucite balls, which are more rigid. The periosteum is stripped from the ribs and left attached, with the intercostal bundles, to the mobilized pleura; the plastic is put between these structures and the ribs.

Another recent development, also not discussed by Naegeli, is resection: lobectomy is occasionally performed, usually for a tuberculoma, but pneumonectomy is more usually performed for tension cavities in the lower lobe, bronchial stenosis, bronchiectasis, or disease with caseation rather than cavitation. With streptomycin to reduce post-operative complications resection may become the treatment of choice whenever indicated rather than a desperate last hope when all else has failed. Postural retention may reduce the size of cavities temporarily, making the patient fit enough for more extensive surgical treatment. The value of sanatorium treatment, carried out conscientiously and continuously, remains of the first importance.

INDUSTRIAL FLUOROSIS

The report[1] on industrial fluorosis to the Fluorosis Committee of the Medical Research Council is an interesting example of the way in which a research problem may be elucidated by the independent observation and intensive team-work of a few individuals. The first step leading to this very full investigation of local conditions, animals, and human beings was taken in 1943, when the occupant of a farm in Fort William, Scotland, situated about half a mile (800 metres) from an aluminium factory, complained that his sheep and cattle were suffering from an unusual form of debility in spite of there being an abundant supply of herbage.

Clinical examination of the affected animals by Professor G. F. Brodie, of the Royal (Dick) Veterinary College, Edinburgh, revealed that their emaciation and debility were due to dental lesions which prevented them from chewing their food effectively. The question of possible ill-health in human beings from pollution of the atmosphere by compounds given off by the aluminium factory was raised in 1944 by Dr. A. M. Fraser, medical officer of health of Inverness-shire, and later in the same year the Secretary of State for Scotland requested the Medical Research Council to conduct an investigation. For this purpose the Fluorosis Committee was set up by the Council in consultation with the Department of Health for Scotland. The investigation comprised analyses of the electrolytic process of manufacture of aluminium and of contamination of the air of the

[1] *Industrial Fluorosis—A Study of the Hazard to Man and Animals near Fort William, Scotland.* Medical Research Council Memo. No. 22, 1949. London: H.M.S.O.

factory and of the atmosphere, soil, herbage, and water of the surrounding area; study of the animals and of the local agriculture; and examination of selected groups of individuals in the factory and among the local residents and of the teeth of adults and school-children. The willing co-operation of the management and workers of the British Aluminium Co., Ltd., greatly assisted the task of the investigators.

The fumes containing fluorine, to which the disorder of the cattle was eventually traced, arise during the electrolytic reduction of alumina, which is dissolved in a bath of the fused fluorides of aluminium and sodium. At the time of the investigation the fumes extracted from the furnace rooms at the Fort William factory were not scrubbed or treated in any way but were allowed to escape from vents opening just above the level of the roof, drifting across the countryside as a dense white cloud of smoke. Inside the factory concentrations of fluorine as high as 3.6 mg. per cubic metre were found in the worst of the furnace rooms, decreasing to about 15% of this figure at a distance of 200 yards (180 metres) and to about 3% at one mile (1.6 km.). Contamination of the soil ranged from 1,010 parts per million in the immediate vicinity of the factory to 66 p.p.m. at 7 miles (11.2 km.) in the direction of the prevailing wind and 13 p.p.m. at 3.3 miles (5.28 km.) at right angles to the wind. Analyses of grass samples gave results closely parallel to those obtained from soil. The teeth of the animals reared on contaminated pastures showed mottling of the enamel, distortion, and deformity. Chemical analysis of teeth and bone showed an excessive fluorine content, and some cases of osteomalacia due to chronic fluorine intoxication were found.

Selected groups of individuals from the workers in the factory and from local residents were then subjected to clinical, radiological, haematological, and biochemical examination. Routine medical histories showed little evidence of an unusual rate of sickness or of organic disease. Radiological examination revealed abnormal appearances in the bones in a proportion—highest (25.4%) in the factory workers who had had the greatest exposure, low (4%) in the local residents, and absent in school-children. Within each broad age group the incidence of abnormalities tended to increase with the length of exposure to fumes. These abnormalities, though very variable in degree and unaccompanied by any clinical disability, resembled those described in the literature as skeletal fluorosis. Excretion of urinary fluorine was roughly parallel to the intensity of exposure. Some mottling of the teeth was found in 5.6% of the children examined, but mottling of a similar type was found in 3.1% and 0.6% of children in two country areas far removed from Fort William.

It is obvious that the severe loss of condition and drop in milk production in affected animals constitute a serious impediment to economic sheep and cattle farming in this area, and though the bone changes found in older factory workers were not associated with any clinical disability they must be regarded as a warning that exposure to fluorine fumes should be limited as far as possible. The report concludes with the recommendation that everything practicable should be done to reduce the amount of fluorine discharged from the factory.

G.P.s AND GERMAN MEASLES

That rubella early in pregnancy may cause defects in the human embryo has been one of the unpleasant surprises thrown up by medical research during the past few years. It is important to get far more exact information on this tragic complication of what is for the sufferer a mild complaint, and in our correspondence columns this week Professor A. Bradford Hill asks general practitioners to join with him in a piece of research from which it is reasonable to expect highly useful results. As Professor Bradford Hill points out, it is desirable to discover the frequency of congenital defects in children born of mothers who catch rubella during pregnancy, the severity of such defects, and their relation to the stage of pregnancy at which infection occurs, and the inquiry may well be extended to such infections as chicken-pox, mumps, and measles. Much of this kind of information could be secured through the Ministry of National Insurance without any breach of the confidential relationship that exists between patient and doctor. The way he proposes to make this inquiry is described in this week's correspondence columns by Professor Bradford Hill, and we hope that general practitioners will respond to the appeal made to them so that more may be known about this unfortunate sequel to German measles.

ROYAL SOCIETY AWARDS

The two Royal Medals for the current year have been awarded to Sir George Thomson, F.R.S., and to Professor R. A. Peters, M.D., F.R.S. Professor Peters was educated at Cambridge University and St. Bartholomew's Hospital, London, and was a pupil both of Sir Joseph Barcroft and of Sir F. Gowland Hopkins. During the war of 1914–18 he spent nine months as a battalion medical officer, and was awarded the M.C. (with bar), but was recalled for scientific work. In 1923 he left Cambridge, where he was Dunn lecturer in biochemistry, and became Whitley professor of biochemistry and a Fellow of Trinity College, Oxford. After early work with Barcroft on the specific oxygen capacity of haemoglobin, Peters turned his attention to vitamin problems, and his name is particularly associated with work on the vitamin-B complex. In 1930 came the first demonstration of the *in vitro* action of a vitamin—the specific response of avitaminous pigeon's brain to Vitamin B_1. This led to proof of the intimate connexion of this vitamin with the metabolism of pyruvic acid. During the recent war Professor Peters directed two teams of research workers on specific war problems. Out of this work came the highly important discovery of BAL or British Anti-Lewisite.

Among the other awards of the Royal Society is that of the Davy Medal to Professor A. R. Todd, F.R.S., for his work in organic chemistry and biochemistry, especially on the B and the E vitamins.

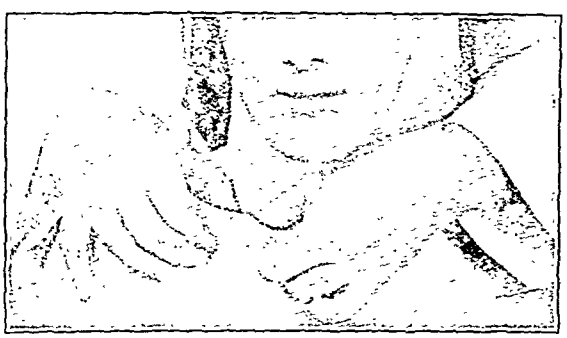
GENERAL PRACTITIONERS' REMUNERATION

Just before we went to press the B.M.A. received a reply from the Ministry of Health on the general practitioners' case for increased remuneration. It is published in the *Supplement* at page 218.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

FRACTURE OF THE CLAVICLE

BY



T. P. McMURRAY, C.B.E., M.Chir., F.R.C.S.Ed.

Emeritus Professor of Orthopaedic Surgery, University of Liverpool

Fractures of the clavicle occur more frequently than any other bony injury, and they are almost invariably the result of transmitted or indirect violence applied to the clavicle through a fall on the outstretched hand or on the elbow, or through contact with the tip of the shoulder. Although compound fractures of the clavicle are not unknown, especially in war injuries, yet this fracture is usually simple, even when resulting from a direct blow on the anterior surface of the bone.

Age Incidence

The fracture is one of the more active period of life, occurring mostly in youths and young adults. As it is commonly caused by a fall, it is usually seen in children or in those taking part in sport. In the elderly, fracture

Examining the clavicle for an ununited, or obscure recent, fracture. (From Mr. Hamilton Bailey's *Demonstrations of Physical Signs in Clinical Surgery*, by permission of the author and John Wright and Sons, Ltd.)

of the clavicle is a comparatively rare accident; at this age a fall on the outstretched hand is more likely to cause a Colles's fracture or an injury to the neck or head of the radius.

Site of Fracture

The fracture usually occurs slightly beyond the middle of the bone where the medial anterior curve meets the posterior curve of the outer segment. Here the strain is greatest. The fracture may also occur toward the inner or outer ends of the bone, the site of the lesion in the inner segment being usually at a point three-quarters to one inch from the sternal attachment of the bone, while the site of the distal fracture is usually the same distance from its acromial attachment.

Symptoms and Signs

These vary according to the type of fracture. With a greenstick fracture, which is common up to the age of 14 or 15 years, the symptoms and signs are slight. Following a fall, the patient, usually a boy, may complain of an ache in the shoulder region but may finish the game he is playing with comparatively little discomfort. Later, persistent aching in the shoulder may draw attention to a clavicular swelling, tender on pressure, but causing little disability and no limitation of movement. Radiographic examination will confirm the presence of a crack in the bone, usually without displacement.

The symptoms and signs which follow a complete fracture in the usual mid-clavicular situation are more severe. The patient complains of a sudden pain in the shoulder region accompanied by a feeling of uselessness in the whole arm and forearm. As a rule, in order to relieve the pain the affected arm is immediately supported by the other hand in an effort to lift the shoulder and prevent the dragging weight across the site of fracture.

On examination of the site of injury it is evident that the clavicle has been broken. The outer sharp, irregular edge of the inner fragment of the bone can be felt projecting under the skin above its normal site, and restoration of the line of the clavicle is possible only by raising the shoulder above its normal position. The radiograph demonstrates that considerable displacement has occurred at the site of fracture, the outer fragment being displaced downwards and the outer end of the inner fragment projecting upwards, leaving a considerable gap between the broken ends.

The symptoms and signs of fracture at the inner or outer end of the bone are considerably modified from those which follow a lesion in the usual situation. As a rule, with either of these fractures there is little displacement and a minimum of deformity. Pain and disability following their occurrence may be so slight that the injury may easily be overlooked unless demonstrated by radiographic examination.

With a fracture close to the inner end of the clavicle impaction on one side of the bone is often present. Some thickening and tenderness are apparent over the injury and movements of the arm are limited because of pain.

When the fracture has occurred towards the outer end of the clavicle there is no displacement if the lesion is situated between the attachments of the acromioclavicular ligaments; tenderness and swelling over the site of injury and subcutaneous haemorrhage indicate the severity of the injury.

Common sites of fracture of the clavicle.

Diagnosis

The diagnosis is, as a rule, an easy matter if the possibility of this injury is borne in mind. The only difficulty is met with in the greenstick fracture of children and in the fractures occurring close to the extremities. A simple subperiosteal haemorrhage may cause some difficulty in clinical diagnosis, but the doubt can easily be settled by radiographic examination.

Complicated Injuries of the Clavicle

On occasion this fracture is accompanied by injury to some of the neighbouring tissues. Thus, fracture of the clavicle may be associated with a lesion of the brachial plexus, particularly of its upper components. After a fall on the point of the shoulder it is obvious that the patient

has sustained a fracture of the clavicle, and unless a careful examination of muscle movements is carried out an accompanying injury to the fifth and sixth cervical nerves may be missed. Because of the pain produced by the fracture the patient naturally keeps the whole shoulder at rest, and it is frequently difficult to separate the loss of power which follows injury to the plexus from the reflex inhibition produced by the fracture.

If the force applied to the shoulder is extreme the fracture may also be associated with a lesion of the whole of the plexus. In this event the differential diagnosis is comparatively simple, and is indicated by the complete flaccidity of the whole of the affected arm, with a loss of sensation over the entire limb below the elbow.

When the fracture has resulted from a violent pull on the arm in a position of full-extension the lower cord of the plexus may be stretched or torn, giving a loss of power in the intrinsic muscles of the hand—a complication which is very difficult to diagnose directly following the injury. Injury to the neighbouring blood vessels may occur also, usually not as a result of traction but following direct injury to the vessels by the sharp surface of the inner end of the outer fragment of the bone.

These injuries can all be diagnosed by a careful examination of the patient, and treatment of the fracture should be delayed until the possibility of these complications has been eliminated.

Treatment

The treatment of this fracture is not difficult, and if a few simple precautions are employed a successful result is to be expected.

Methods

Figure-of-8 Bandage.—The objects of treatment are to raise the shoulder to bring the two fragments of the broken bone into alignment; to pull back the shoulder to prevent overriding of the broken bone; and to restore full length, with fixation in that position until clinical union has occurred. The simplest and most generally satisfactory method of accomplishing these aims is by the use of the figure-of-8 bandage. Two or three large flannel or calico bandages are employed, passing round each shoulder in turn and crossing each other posteriorly. These bandages are applied firmly, the shoulders being pulled back by each turn of the bandage. When the bandages have been firmly fixed in this position by pinning or tying, a firm loop of bandage is attached to each shoulder loop in front across the chest. This simple method of retention keeps the original figure-of-8 in position and prevents the bandage slipping from the shoulder, which would destroy the fixation.

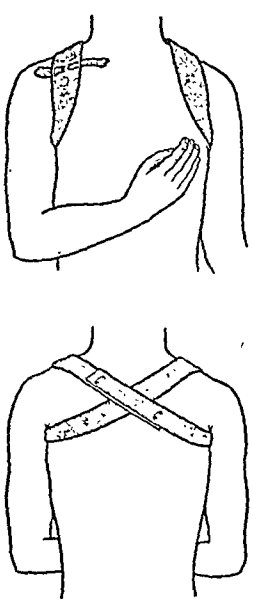


Diagram illustrating the pulling back of the shoulders without the anterior bandage support. (From Mr. George Perkins's *Fractures*, by permission of the author and Oxford University Press.)

When fixed in this way the patient is encouraged to use the hand, fingers, and elbow in order to prevent stiffness of these joints, a complication which is to be feared in the adult patient. After four weeks clinical union is usually satisfactory, and the patient may be allowed freedom from all control, gradually restoring full movements at all the joints by voluntary exercises. A sound, fully functioning limb is to be expected, with no disability except for the presence of a bony nodule at the site of fracture.

Occasionally, especially if the fracture has been comminuted, a spike of bone is present at the fracture site projecting under the skin. This spike should not be interfered with or removed, as it rapidly diminishes in size and gradually becomes rounded.

T-Splint.—To obtain the same fixation a T-shaped wooden splint may be used. This is placed on the patient's back, the long arm of the T extending from the sacrum to the level of the middle of the scapulae. The cross arms of the T extend behind each shoulder, and to these cross arms the shoulders are firmly bandaged, stability of the splint being obtained by fixing the main portion to the body and pelvis. The object of fixation and raising the shoulder can be attained equally well with the less cumbersome figure-of-8 method, and there are no special advantages in the use of the splint.

Strapping Method ("Sayre's").—This method of fixation by applying strapping round the arm and chest to pull back the shoulder and pull the elbow upwards and forwards has been gradually abandoned. It was the procedure generally adopted and taught in the textbooks for many years, but there are so many disadvantages in the method that it has now been largely superseded by the less troublesome fixation by bandages. In applying this form of treatment the arm was first pulled backwards and fixed to the chest by wide strapping, while by a second strap the elbow was pulled forward and upward with the hand and fingers firmly applied to the chest wall. The subsequent rigidity of all the joints of the limb usually required a long period of physiotherapy for their relief, and in many instances full movements could not be restored to the adult patient.

Treatment in Recumbency.—For those few patients in whom the presence of a nodule on the substance of the bone would be considered to be a great deformity, better alignment and a smaller mass of callus can be secured by treatment in recumbency. The patient is treated recumbent on a firm mattress with a small sandbag placed between the shoulders. This position is maintained for three to four weeks. As a result the alignment is improved and less callus is formed, but the confinement to bed for a month is usually considered to be unbearable for the treatment of a comparatively simple injury.

Intra-medullary Wiring.—An attempt has been made to restore and maintain the exact alignment of the bone by fixing the fragments in position by means of an intra-medullary wire. This is introduced through an opening in the outer or inner fragment and threaded along the medullary cavity of both fragments. The method is not to be recommended; snapping of the wire has occurred on several occasions and the presence of the wire does not stimulate but rather retards bony union.

Sequelae of Fracture of the Clavicle

If treated by the simple figure-of-8 bandage without fixation of the hand and fingers the result is usually excellent Full movements are gradually restored to all the joints and the patient is left with no disability. Under certain circumstances the result is not so satisfactory, and subsequent trouble and disability may be encountered.

Rigidity.—Limitation of movement may affect any of the joints of the upper limb, either as a direct result of the fall or as a consequence of inefficient treatment. At the

time of the accident the shoulder joint or the muscles of the shoulder region may be injured, and as full movements of the joint cannot be maintained until the fracture is united limitation of movement may become obvious when all fixation has been removed. The limitation may be reduced by the patient's own efforts during treatment, but massage and exercises may be needed at a later date.

A much more serious state of rigidity is encountered in those patients, especially adults, in whom the hand and fingers have been kept at rest during the course of treatment. Massage and voluntary exercises help to diminish the rigidity, but as a rule a considerable disability is left if the possibility is forgotten.

Non-union.—Non-union of a fracture of the clavicle is a comparatively rare complication, especially when the fracture is simple. It may occur in spite of correct and efficient treatment, but is usually seen only when treatment has been neglected or when a portion of the bone has been removed in a compound fracture. As a result of non-union the patient usually complains of aching and a feeling of clicking when the arm is used. There is usually little or no tenderness over the fracture, but the movements of the fractured surfaces on each other are disabling.

Treatment of Non-union

On occasion, union of the fractured bone can be obtained by continuing the fixation for a longer period. If the fracture is comparatively recent a further period of fixation of four to six weeks may be sufficient to produce a sound, painless union. When non-union has been present for a considerable period even prolonged fixation is usually unsuccessful in producing union, and operative interference is advisable.

Bone Grafting.—In attempting to produce bony union a bone graft is applied to the site of fracture. An inlay graft is placed in a deep slot cut on the antero-inferior aspect of the clavicle and reduction maintained as in a fresh fracture of the bone. Because of the difficulty of obtaining complete fixation of the fracture the bone-grafting operation may not be successful, and if the operation has failed on the first occasion the prognosis is much worse if a further attempt is made.

Partial or Complete Removal of the Clavicle.—If bone grafting has failed and the patient still complains of pain and disability a considerable improvement in the condition may be effected by the removal of a large section of the clavicle from either side of the fracture. As a result of this the painful clicking of the fractured surfaces is eliminated, and though the shoulder tends to fall forward to a slight degree the usefulness of the limb is increased. Because of the possibility of the re-formation of the clavicle which has been removed it may be advisable on occasion to remove the whole of the bone, which, though apparently a radical procedure, does little to reduce the strength and usefulness of the affected limb.

The Ministry of Health has notified hospital boards and committees that it will not set up any central machinery for dealing with redundant, worn-out, or obsolete equipment in hospitals. Boards and committees should dispose of such equipment as before. Serviceable items of equipment which become redundant in any hospital should be transferred to another hospital where they can be used. No cash adjustment should be made for the transfer, but it should be recorded. Hospitals holding equipment issued on loan during the war under the Emergency Hospital Scheme should use it where possible. Schedules of this equipment should be prepared and sent to the Ministry of Health, Supplies Division I, Whitehall, London.

SURGICAL TRAVELS IN COLOMBIA

BY

RONALD W. RAVEN, O.B.E., F.R.C.S.

Honorary Professor, National University of Colombia; Surgeon to the Westminster Hospital (Gordon Hospital); Surgeon to the Royal Cancer Hospital

Surgical travels in other lands are full of interest, and are valuable for the development of understanding between the countries involved. Our country always welcomes the surgeons of other lands to her surgical centres, and many avail themselves of the facilities provided. Others find it impossible to make the journey, but they can be reached and helped when British surgeons undertake such a mission as is described in this paper. The National University of Colombia extended an invitation to Dr. Lawrence H. Morris and myself to visit Bogotá in order to deliver a course of lectures and perform surgical operations. This invitation was accepted, and we left England on April 26, 1949. As this is the first occasion such a visit has been made, it is felt that a record of it might be of interest.

Historical Background of Colombia

Colombia is the only country in the New World which bears the name of the discoverer, Christopher Columbus. The exploration of this region was carried out by his companions and contemporaries, and resulted in the foundation there of Santa Marta in 1525 and Cartagena in 1533. These ports developed into two of the most important centres of this vast continent and became the scene of many struggles and sieges in bygone days. In some of these expeditions Sir Francis Drake was actively engaged. The last great attack which Cartagena suffered in the colonial age was in 1741, when Sir Edward Vernon arrived at the head of the greatest army ever to reach the coasts of the Caribbean Sea.

Colombia was the cradle of the great Chibcha and Kimbaya Indian civilizations, which fell before the Spaniards. Santa Fe de Bogotá was founded by Jiménez de Quesada after a heroic expedition, and the future capital of the country came into being. Its history is bound up with the revolt of the Comuneros and the beginnings of Colombian science under Mutis and Caldas. Finally there came the great revolutionary movement organized by Bolivar, Nariño, and Santander, which transformed the country and ended in its independence being established. The Colombians have never forgotten the help they received from the British soldiers in their fight for freedom.

Geographical Facts

Colombia extends over an area of nearly half a million square miles of land in the north-western region of South America. It is the only country in this continent to face two great oceans, since its western seaboard opens on the Pacific Ocean while its northern coastline looks out on that portion of the Atlantic Ocean which forms the Caribbean Sea.

The outstanding feature of the country is the gigantic mountain ranges of the Andes, which rise in the Caribbean region and continue southward across the continent. This great mountain system spreads out into three main ranges, united in the south-west and opening towards the north. Thus on the left is the Western Cordillera of Chocó, in the middle the Central Cordillera of Quindio, and on the right the Eastern Cordillera of Sumapaz. Scattered among these mountain ranges are high tablelands where the population is denser, especially in the eastern region. To the east and south-west of the Eastern Cordillera is an immense plain traversed by the great rivers Caquetá and Vichada, which empty respectively into the Amazon and the Orinoco.

The country lies entirely within the Tropics, but the climatic conditions vary greatly. The line of the Equator traverses its southern part, but when the rivers, forests, and lowlands are left behind, temperate valleys and plateaux are reached where there is perpetual springtime with orchards and flowers in full bloom; and rising high above the plateaux are the mountains.

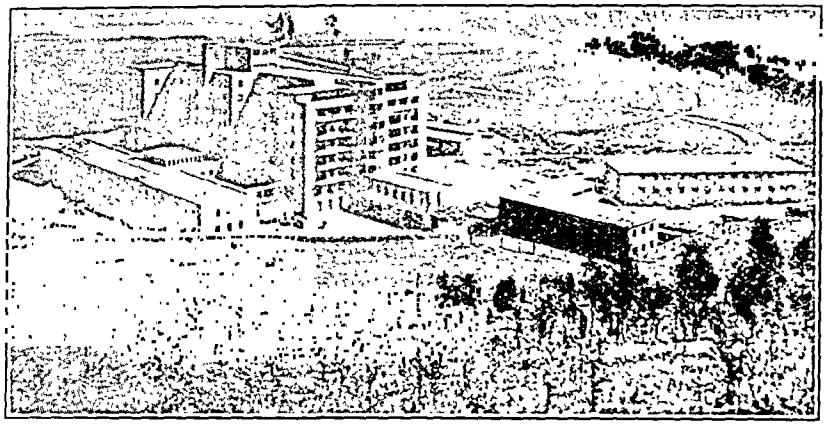

FIG. 1.—The San Carlos Hospital, Bogotá.

covered always with snow. The dry and wet seasons alternate at intervals of three months, starting with a dry period from December to February.

Colombia is a land of contrasts, and these are most striking when seen from an airplane. The landscape is always changing, revealing interwoven greens, browns, and blues. The huge mountain ranges, their jagged summits rising up against the sky, the rivers winding in the valleys, and the numerous primeval forests scattered throughout the country are an impressive sight.

The flora is abundant and diverse, and botanists affirm that more than fifteen thousand specimens have been described. Many of the wild plants, like the chupahuevo and matarrotón, are said to possess medicinal properties; and parasitic plants abound, notably the orchids which grow in rich profusion on the trunks of trees.

On the plains and in the valleys immense herds of cattle graze, and sheep and pigs are being reared on an increasing scale. Also, horses are imported from England to improve the local breeds. In the jungle there are various wild animals, including jaguars, tapirs, boars, deer, pumas, foxes, and bears, in addition to numerous species of monkeys and squirrels. The rivers contain the crocodile, the gliding eel, small salmon, the bagre, and the captain fish. Amongst the marshes and lakes are found waterfowl, heron, and wild duck, and on the moors quail, partridge, and pigeon. It is possible to see on the mountain crags a hawk or the rare condor. Many varieties of butterflies exist here, and numerous kinds of parrots, macaws, and parakeets.

There is a very interesting area known as the Macarena Hills, which is infested with monkeys and where yellow fever is rife. Consequently it has never been explored by man until recently. The control of yellow fever by inoculation has now made this possible. A research centre has been established with its headquarters in Villavicencia, and we had the opportunity of meeting and talking with the director of this work. A number of interesting biological investigations are being carried out, and it is hoped to extend these researches in the future. This appears to be a fruitful field for capable trained investigators.

The Travel Itinerary

We went to New York by sea, and, after spending one night in that city, travelled by air to our destination in Colombia. It was a grand flight over Miami in Florida, Cuba, and Jamaica; the beauty of the islands in the Caribbean Sea is most impressive. We reached Colombia at Barranquilla, a fine international port which is linked by the Magdalene River with the heart of the country. Here we received a warm welcome before proceeding by air to Bogotá, the capital city, where our main work was to be done. We were met by a deputation which included the Minister of Hygiene, the Director of the National Radium Institute, the representatives of the British Council, and a number of professors and doctors.

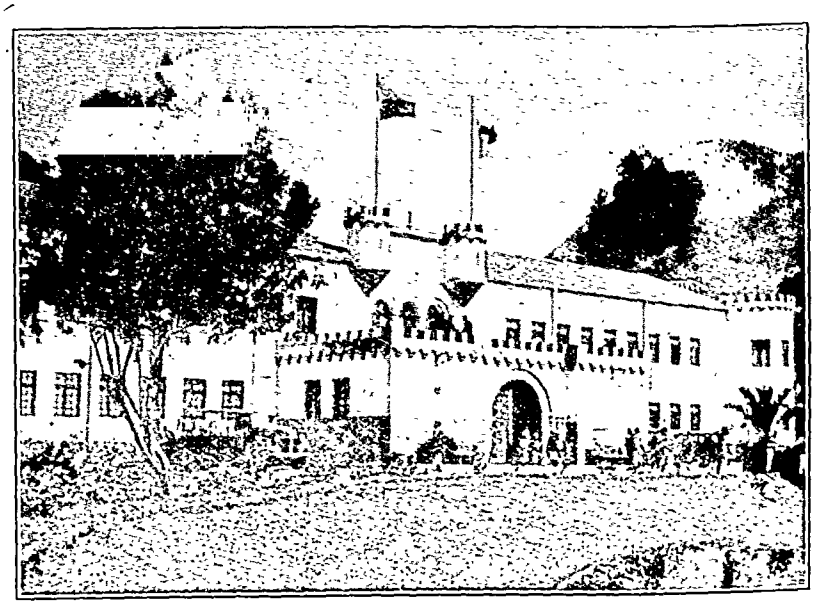
Bogotá is situated on the great plain—the Sabana de Bogotá—at a height of 8,500 feet above sea-level. It was established over 400 years ago, and is divided into old and modern sections, the former of which has a distinctly Spanish atmosphere, with narrow winding streets, big balconies on large colonial houses with gay patios, and peaceful little squares. Possessing a population of more than 600,000 persons, it is the centre of the political and cultural life of the country. The National University of Colombia occupies an area of 400 acres and has a large faculty of medicine. We spent four weeks working in Bogotá, and then left by air for Medellin, the capital of the rich department of Antioquia. This city was founded in 1674, and is recognized as one of the greatest industrial centres of Colombia. We worked in the University of Antioquia for three days and then proceeded by air to Cartagena.

Cartagena is a historic city of great grandeur situated on one of the beautiful bays of the Caribbean Sea. It is an important intellectual centre, with its university, the Academy of History, and the Naval School of the Colombian Navy. We spent a short period of two and a half days at work in the university. From Cartagena we went by air to the U.S.A. and attended the Joint Meeting of the American Proctologic Association and the Proctological Section of the Royal Society of Medicine, which was held in Columbus, Ohio. From Columbus we flew to New York and returned to England by sea.

Surgical Work in Bogotá

At the National University a large number of medical students are being trained. The curriculum extends over a period of six years, and after qualification resident appointments in the hospitals are available. Facilities are also provided for those who desire to make a study of special branches of medicine and surgery; these graduates often spend a period in the specialized clinics in England and the U.S.A. Many expressed a wish to come to England for this purpose.

The teaching hospitals vary greatly in size, the largest containing 1,200 beds. The treatment of cancer patients is mostly carried out in the National Radium Institute—a school of the University—whose director is a professor of surgery. This very active surgical centre also possesses a radiological department divided into therapeutic and diagnostic sections, a pathological department, and a statistical department. A large number of undergraduates attend the practice of this hospital.



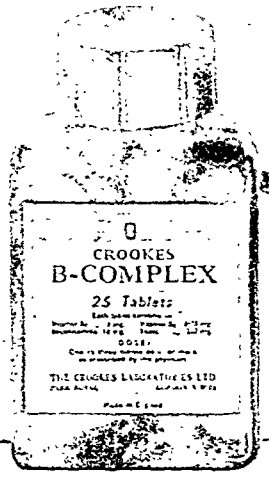


FIG. 2.—The Military Hospital, Bogotá.

When the clinical condition suggests

NUTRITIONAL DEFICIENCY

IT is not always easy to determine which particular factor of the complex is lacking. In such cases administration of the whole vitamin B complex is to be preferred.

Crookes B-Complex Tablets provide a special strain of yeast, with standardised amounts of vitamin B_1 and B_2, and nicotinamide. They are agreeably sugar-coated, thus overcoming any objection to taste or smell.

CROOKES

Preserving the Pre-Natal Balance

As pregnancy advances, the main concern of the doctor in charge is to preserve the nutritional balance of the mother against the undeniable demands of the foetus.

Even when all the protective foods required are available in sufficient quantity, and the mother's appetite is normal, there is still everything to be said for the rationale of taking prophylactic measures against the development of latent deficiencies. Pregnavite supplies, in rational dosage, precisely those protective nutritional factors any shortage of which will undoubtedly weaken the mother's reserves and may also imperil the pregnancy.

* The recommended daily dose provides: vitamin A 2,000 i.u., vitamin D 300 i.u., vitamin B_1 0.6 mg., vitamin C 20 mg., vitamin E 1 mg., nicotinamide 25 mg., calc. phosph. 480 mg., ferr. sulph. exsic. 204 mg., iodine, manganese, copper, not less than 10 p.p.m. each.

PREGNAVITE

Protects the Mother . . . Safeguards the child

A single supplement for safer pregnancy*

VITAMINS LIMITED, UPPER MALL, LONDON, W.6

An important addition to the hospitals in Bogota is the new San Carlos Hospital (Fig. 1) for the medical and surgical treatment of tuberculosis. It embraces the most recent developments in hospital design, and is equipped with every modern device, including its own laundry. From its lay-out, especially in connexion with the wards and operation theatres, this hospital may be considered a model of its kind.

In addition to the civil hospitals there is the military hospital (Fig. 2)—a well-equipped institution beautifully situated amongst the hills.

The staffs of the hospitals are extremely keen and capable. A number of surgeons are engaged in various specialties, which include thoracic, gynaecological, and neurological surgery, urology, and proctology. In addition to routine undergraduate surgical teaching, clinical conferences and staff rounds are organized in each hospital and are well attended. On such occasions a number of patients with various lesions are shown and the diagnosis and treatment are discussed; or a definite subject is chosen and presented by a staff member, this being followed by a discussion. Original investigations are carried out in the laboratories, and facilities for pathological, clinical, and experimental research are provided.

There are two excellent clinics in Bogotá containing over 100 beds for the treatment of private patients. I was shown over them and was impressed with the facilities provided.

Most of our surgical work was carried out in the National Radium Institute, where every help was given by the director. Operations were also performed in the other teaching hospitals in the city.

The daily programme was a full one, the general plan being as follows. Surgical operations and anaesthetic demonstrations began at 8 a.m. and continued until 1 p.m. on four days a week, and until 11 a.m. on two days a week so that clinical meetings could be held. The staff were present at these meetings together with surgeons and doctors from other hospitals. The afternoons were devoted to discussions with staff members of hospitals, the examination of patients, or other work. Formal lectures were delivered daily at 6 p.m. in the faculty of medicine of the National University. These lectures comprised both general and special subjects. Amongst the former were such topics as "The Contribution of Great Britain to World Surgery," "The London Blood Transfusion Service," etc. The special group included the surgical treatment of cancer in various sites, anaesthesia, and lectures on war surgery. This was the first occasion on which lectures on surgery in war had been given in the country.

The National Academy of Medicine is an important learned society where papers embodying original work are presented. We had the privilege of addressing this academy at a special session. I also addressed the Congress of Gynaecologists meeting under the auspices of the Bogotá Surgical Society at its San José Hospital. In addition an address was given to the National Colombian Society of Gastro-enterology.

Medellin and Cartagena

The teaching hospital in the former city is San Vincente, which is a large and busy institution. Surgical operations and anaesthetic demonstrations were carried out and lectures were delivered in the medical faculty of the University of Antioquia.

At a special meeting of the academic council of the University of Cartagena it was pleasing to hear the Director of Education and the Rector speak of the close bonds of affection which have linked Great Britain and Colombia together over a period of many years. We worked in the teaching hospital of Santa Clara and lectured in the faculty of medicine of the University.

Malignant Disease in Colombia

During my stay I saw a large number of patients with malignant disease and also studied statistical reports. As in Great Britain, many of the patients apply for treatment when the disease is far advanced. It is important to establish an anti-cancer campaign there, and I discussed this subject with the profession. They are very anxious to develop this work, and realize the importance, both for the lay population and for doctors, of an educational programme dealing with the early symptoms of this disease. It is hoped that this work will soon begin, and that it will result in patients being treated much earlier in the disease than at present.

Regarding the incidence of various types of malignant disease, I was struck with the number of cases there were of sarcoma and other tumours of bone. All types of case were seen, and from the records there did not appear to be any outstanding aetiological factor.

Carcinoma of the cervix uteri is one of the commonest forms of this disease, and the same applies to the breast. A fair number of cases of epithelioma of the vulva and vagina are seen, and certain parts of the alimentary canal appear to be affected more frequently than others, common sites being the mouth, oesophagus, and stomach. As in this country, every effort should be made to diagnose carcinoma of the stomach much earlier in its development than at present. There appear to be fewer cases of carcinoma of the colon and rectum than with us.

General Impressions

The vastness and the grandeur of the country leave an indelible impression upon the mind of the visitor, and distances are such that air travel is essential. The medical profession received us with great friendliness, and it is a pleasure to recall the kindnesses we received. The hospital arrangements are good, with units varying in size up to a bed complement of 1,200. It is obvious that excellent surgical work is being done there, and the surgeons are keen and enthusiastic. There is a desire to progress and to learn new methods and techniques. It is hoped that facilities will be available for more of these keen young men to visit Great Britain and see the work here. Many Colombians wish to learn the English language, and in this and many other ways the British Council is doing excellent work.

It is a pleasure to thank the National University of Colombia for the invitation to undertake these travels, and also the University of Antioquia and the University of Cartagena for kindly asking us to visit them. The British Ambassador in Colombia gave us all possible help during our stay, and the Colombian Ambassador in London was most helpful in connexion with our visit. The medical profession in Colombia and many other friends showed us great kindness. The British Council made many arrangements for us, and its representatives in Colombia were most helpful throughout.

HEALTH EDUCATION

National Conference in London

Lord Woolton, president of the Central Council for Health Education, opened a two-day national conference at the Central Hall, Westminster, on November 8. The conference was attended by 700 delegates from local health and education committees and voluntary organizations, with many medical officers of health and directors of education. An exhibition, opened by Sir Arthur Hobhouse, chairman of the County Councils Association, was held in association with the conference. This was much more than the usual miscellaneous display of pictorial material. It was planned in five sections, comprising the nature, needs, environment, and diseases of man, and the social and health services, each illustrated by means of models, films and film-strips, charts, posters, photographs, and booklets.

At the opening session Professor ANDREW TOPPING, of the University of Manchester, made a striking contribution in which he blamed the medical profession for the general lay attitude towards sickness—namely, the attitude that anatomy, physiology, and pathology were esoteric subjects, beyond the comprehension of the layman. Admittedly under present conditions it was difficult for the doctor to find time for frank discussion with inquiring patients instead of making an arbitrary diagnosis and giving a scribbled prescription, but eventually he hoped that a large part of the resources of the medical profession would be devoted to the things that really mattered—the education of the public, the prevention of disease, and the control of the basic factors that produced disease.

It was an unpalatable fact. Professor Topping went on, that 90% of the minor illnesses from which we suffered were due to our own fault as individuals, parents, or members of the community. It was so easy for the ill person to consider himself a victim of something beyond his control, and there was still a regrettable tendency to "enjoy" ill-health, to be sentimentally avid for sympathy, and to be proud if one's illness was dignified by a high-sounding name. He believed that there was more scope for education in the field of infectious diseases than in any other. The vast majority of such diseases were avoidable by human endeavour. With one important exception—infantile paralysis—it was known exactly how infection was spread. The public should be told the facts in very simple language. He pleaded for an abandonment of the prudery which made the task of educating the public unnecessarily difficult. Euphemisms cut little ice. The public should be told in plain words how bowel diseases and food-poisoning originated and were spread.

Professor W O. LESTER SMITH, of the University of London, emphasized the importance of the school nurse. A good school nurse exerted the influence of a missionary. It would be an admirable thing if once a year school doctors and nurses attended a staff conference with health education as the sole subject on the agenda, when every aspect of the curriculum could be brought under review in relation to problems of health.

Second Session

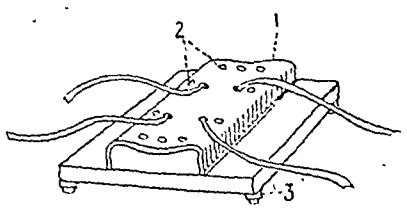
The second session was presided over by Sir WILSON JAMESON, who reminded the conference that the Central Council was the child of the Society of Medical Officers of Health. The policy of the Government was now to reduce its direct grants in the belief that the Central Council would have a more independent, and in some ways a more useful, role under the aegis of local authorities.

Mr. D. R. HARDMAN, M.P., Parliamentary Secretary to the Ministry of Education, discussed the task of the health educator. His function was not to teach facts or even to develop skills, but to encourage an attitude of mind which would attract the child or the adult of the community generally to the ideal of healthy living.

Dr. ROBERT SUTHERLAND, medical adviser and secretary to the Central Council, said that the Council was just emerging from a period of considerable despondency and frustration. About two years ago it was told that, for reasons which were quite logical, the Government proposed to reduce its direct grant, at the same time increasing its grants to local authorities in the expectation that from such authorities there would be increased support for health education. The associations of local authorities, with which the subject was discussed, felt that they could not ask their individual authorities to double their subscriptions, as has been suggested, in order that the Central Council might not only maintain its existing services but improve them. The Central Council had been obliged to review its functions and to make very serious retrenchments, which was uncomfortable for everybody concerned. He believed, however, that as a result of this experience it had gained new life and new force and had directed its services into channels of even greater value.

Those who were working in preventive medicine, Dr. Sutherland continued, had been going through a similar experience as a result of the changes which had been brought about by the National Health Service Act. Many public health workers had felt that a large part of their life's work had been taken from them. He believed that such a period of tension was a necessary preliminary to a new orientation and re-direction of effort and a great surge forward into new fields of activity. There was every reason to believe that the local authorities, and those concerned with preventive medicine and with the teaching hospitals, and with education generally, were awakening to a new realization of the scope of health education in their own fields.

Professor R. H. PARRY, of the University of Bristol, said that they all hoped that the family doctor in the future would have sufficient time to be also the family friend and adviser. A healthy adult, however, did not need expert medical knowledge to maintain his fitness and lead a healthy life. "There is no need for him to qualify as a doctor—in fact, life tables prove that he would shorten his life by so doing." What he wanted was a sound knowledge of elementary biology. He must know the capabilities of his own body, and he might need an occasional word of advice on special problems that arose. Professor Parry went on to criticize certain forms of sex education. He was convinced that sex lectures to classes in senior schools often did more harm than good, merely stimulating the curiosity of the child. Training in biology in schools should supply sufficient knowledge, so that with a little further instruction, preferably from parents, the child or adolescent could understand his personal problems.



Conference Dinner

Lord Woolton presided over a dinner held in connexion with the Conference. He mentioned that it had been his hope as Food Minister that the children of the country would go through the war unscathed. If they had come through rather better physically than they had been at the beginning it was a matter for great thankfulness. Dr. Charles Hill, in proposing the toast of "The Guests," said that there could be no greater tribute to the Central Council for Health Education than the distinction of the guests, who included the Lord Chancellor representatives of the Ministries of Health and Education, of the departments of public health and social medicine at the universities, and of the associations of local authorities Viscount Jowitt made a response in a jocular vein in which he said that the real test of the value of the doctor was to see what happened when the patient had not done what he advised Mr Walter Elliot, M.P., proposed the health of local authorities, and expressed the hope that in future they would be more closely concerned with health education. Sir Howard Roberts, clerk to the L.C.C., said that local authorities needed all the "health" they could get. They had undergone some severe operations, with the removal of some of their health functions, though health education was still left to them. Sir Wilson Jameson, Chief Medical Officer of the Ministry of Health and Ministry of Education, said that the Central Council had been able to attract the help of large numbers of able and public-spirited people who had given generously of their time. In particular an immense debt of gratitude was due to Dr. Charles Hill, a former president of the Council, for the work he had done in public health education. Other speakers were Dr. Maurice Williams (president, Society of Medical Officers of Health), Mr. F. L. Freeman (president, Association of Education Officers), Dr. E. K. Macdonald, and "Fougasse" of *Punch*.

Preparations and Appliances

WEIGHT-BEARING DEVICE

Dr. W. S. TEGNER, physician to the Arthur Stanley Institute for Rheumatic Diseases (Middlesex Hospital), writes: The apparatus here illustrated has been designed by two physiotherapists of the institute to replace the conventional roller-skate as a means of obtaining non-weight-bearing movement, especially in the hip-joint after vitallium-mould arthroplasty. It has the advantages over the roller-skate of being designed for the job, of being mobile in all directions, of having a wide base, and of being easily used even when the limb is in plaster. It consists essentially of a wide-grooved wooden plate lined with "sorbo" rubber and diffusely perforated to allow of firm fixation by bandage to different sizes of limbs. While it has proved particularly useful in treatment after hip arthroplasty, it has also a wide range of other uses when non-weight-bearing exercises are required. It is being made by Messrs. Stanley Cox, and will be known as the Boltworth skate.

1, Rubber-cushioned surface for limb 2, Variety of holes for ties. 3, Ball castors.

AUREOMYCIN AND CHLOROMYCETIN

The Ministry of Health has issued the following memorandum:

These drugs are scarce and costly. Their use can be justified only for conditions in which they are considered likely to be beneficial. To ensure that the available supplies are used to the best advantage, the Ministry of Health has arranged to purchase all available supplies of both drugs and to distribute them through regional hospital board centres previously used for distribution of streptomycin. Hospitals outside the National Health Service will be able to obtain supplies of aureomycin and chloromycetin from these centres on payment. These arrangements will operate from November 21, 1949.

On the advice of the Medical Research Council it has been decided for the present to confine the use of these drugs to the treatment of the following conditions:

Aureomycin.—Suspected cases of ornithosis; proved cases of undulant fever (brucellosis), lymphogranuloma inguinale; severe cases of atypical pneumonia in which there is good reason to believe that the cause is a virus.

Chloromycetin.—Suspected cases of ornithosis; proved cases of undulant fever (brucellosis), lymphogranuloma inguinale, typhoid fever, paratyphoid fever (severe), salmonella septicaemia.

These categories are under constant review and may be added to from time to time in the light of current expert advice.

The Regional Distribution Centres are listed below.

Aureomycin and Chloromycetin Distribution Centres

Area No. and Board	Distribution Centre	Tel. No.
Area No. 1 Newcastle R.H.B.	Newcastle-upon-Tyne General Hospital, 418, Westgate Road, Newcastle, 4	Chief Pharmacist New. 35211
Area No. 2 Leeds R.H.B.	Leeds Blood Transfusion Laboratory, The Bridle Path, York Road, Seacroft, Leeds	Leeds 45091/3
Area No. 3 Sheffield R.H.B.	City Hospital, Hucknall Road, Nottingham	Nottingham 66292 (3 lines)
Area No. 4 East Anglian R.H.B.	Addenbrooke's Hospital, Cambridge	Chief Pharmacist Cam. 4451
Area No. 5. N.W. Met. R.H.B.	West Middlesex Hospital, Twickenham Road, Isleworth, London	Chief Pharmacist Hounslow 2311
Area No. 6 N.E. Met. R.H.B.	Mile End Hospital, Bancroft Road, London, E.1	Physician, Supt. Advance 2873/7
Area No. 7 S.E. Met. R.H.B.	Grove Park Hospital, Lee, London S.E.12	Lee Green 1077/8
Area No. 8 S.W. Met. R.H.B.	South London Blood Supply Depot, Benhill Avenue, Sutton, Surrey	Vigilant 0068
Area No. 9 Oxford R.H.B.	United Oxford Hospitals, Churchill Hospital, Headington, Oxford	Chief Pharmacist Oxford 48651
Area No. 10 South Western R.H.B.	Ham Green Infectious Disease Hospital and Sanatorium, Bristol	Bristol 31165
Area No. 11 Wales R.H.B.	City Isolation Hospital, Canton, Cardiff	Medical Supt. Cardiff 960
Area No. 12 Birmingham R.H.B.	Selly Oak Hospital, Birmingham	Medical Supt. Selly Oak 1361
Area No. 13 Manchester R.H.B.	Manchester Royal Infirmary, Manchester, 13	Chief Pharmacist Ardwick 3300
Area No. 14 Liverpool R.H.B.	Fazakerley Sanatorium, Liverpool, 9	Medical Supt. Aintree 2324

The Joint FAO and WHO Expert Committee on Nutrition held its first session at Geneva on October 24–28 under the chairmanship of Lord Horder. The committee recommended devising other methods of supplying prophylactic doses of iodine than adding it to table salt, especially in undeveloped areas. WHO is to gain information on the prevalence of pellagra, and to conduct an inquiry into the various forms of kwashiorkor. A recommendation was addressed to FAO on the preparation of an international code of analytical methods for the determination of vitamins in foodstuffs. The following were the members of the Joint Committee: Professor G. Bergami (Italy), Professor J. F. Brock (Union of South Africa), Professor Josue de Castro (Brazil), Professor M. J. L. Dols (Netherlands), Lord Horder (United Kingdom), Dr. V. N. Patwardhan (India), Dr. J. Salcedo (Republic of Philippines), Dr. W. H. Sebrell (U.S.A.), Dr. Hazel Stiebeling (U.S.A.), Professor E. F. Terroine (France).

Reports of Societies

NEONATAL PNEUMONIA AND TOXOPLASMOSIS

At a meeting of the Liverpool Medical Institution on October 20, with the president, Professor Charles Wells, in the chair, Dr. A. H. CRUICKSHANK read a paper on "Experimental Studies of Neonatal Pneumonia."

Lantern slides illustrating some of the common conditions affecting the lungs of babies who had died at birth, or within a few days of birth, were first shown. These included macroscopic views of atelectatic lungs with marked interstitial emphysema, microscopical views of polymorphonuclear cells in the alveoli of a stillborn infant, inhaled squamous debris from the infant's own skin, macrophages filled with phagocytosed meconium, and alveoli lined by hyaline membrane. These appearances were then discussed in relation to the respiratory movements that have been observed clinically and experimentally by various workers. Some authorities had suggested that the unborn human infant normally inhaled amniotic fluid. The results of experiments in which amniotic fluid, and its various constituents and contaminants, had been introduced into the lungs of adult rabbits by intratracheal injection were then presented. Meconium was shown to have a harmful effect by virtue of the intensely irritant bile salts which it contained. The desquamated squamous cells found in human amniotic fluid were then shown to be capable of causing a foreign body giant-cell reaction in rabbits' lungs; and, finally, collapse and leucocytic migration were demonstrated after the injection of cell-free, sterile, rabbit's amniotic fluid. A similar reaction was obtained after the injection of normal saline solution.

It was concluded that it must be abnormal for amniotic fluid to reach the infant's alveoli, and that it did so only as a result of a difficult labour, or of some other cause of foetal asphyxia. If the reaction in the lungs of adult rabbits was an index of the reaction in infants' lungs, inhalation of much amniotic fluid would be likely to cause a fatal atelectasis. In four or five days' time a foreign-body reaction might be found experimentally, but such a reaction was rarely noted in material from human infants in the neonatal period. That a foreign-body reaction could occur in a baby was shown in a slide from an infant surviving for four days with amniotic debris in its lungs. The rarity of such a finding pointed to the rarity of survival for as long as four days in these cases.

Toxoplasmosis

Dr. A. MACDONALD read a paper on toxoplasmosis, in which he discussed the laboratory diagnosis of the condition by methods including the serum neutralization test on the chorio-allantois of the developing chick and a complement-fixation test using antigen prepared from infected chick embryo tissue. Three cases of congenital toxoplasmosis in Liverpool gave similar results with both types of test. Positive complement-fixation tests were obtained in three out of 100 "normal" sera, presumably as a result of symptomless infection. It was difficult to assess the significance of a positive test in patients who had only one or two of the clinical signs often associated with the disease. Preliminary investigations showed an increased incidence of positive complement-fixation tests in infants with anencephaly, chorio-retinitis, and mental retardation, as compared with normal children. He emphasized that blood from both mother and infant should be examined preferably by at least two types of serological test.

In the discussion which followed, Professor N. B. CAPON discussed the possibility of other infections besides toxoplasmosis damaging the embryo and foetus. Dr. J. BERKSON said that from 1943 onwards there were frequent references in the American ophthalmic journals to the retinal changes due to toxoplasmosis. The pictures illustrating the retinal lesions accompanying these articles did not appear to him to differ from those seen regularly in the past and labelled congenital

coloboma, or old congenital choroido-retinitis. One of the three cases discussed by Dr. Macdonald was a patient of Dr. Berkson's, seen in March of this year. He was a boy aged 9 who presented a convergent strabismus in a microphthalmic eye, with a large area of old choroido-retinitis. He appeared to be mentally defective. The case was shown to the speaker's colleagues as a case of toxoplasmosis, and *x*-ray examination of the skull showed areas of cerebral calcification. Dr. Macdonald finally confirmed the diagnosis by showing a positive serological reaction in the boy and in his mother.

Dr. H. G. FARQUHAR said that the incidence of toxoplasmosis in man was not accurately known. It was a common parasite of animals, being found in cats, dogs, mice, rabbits, canaries, and sparrows, as well as in many other animals. Clinically, it appeared to occur in man in four more or less distinct forms: (1) a congenital infection, in which the foetus was affected *in utero*; (2) an encephalitis affecting older children; (3) an acute febrile illness in adults with a rash rather similar to that of typhus, and with a high mortality; (4) an apparently symptomless form affecting adults, which could often only be diagnosed by specific tests, but which might be confirmed in the female by the birth of a child affected with the disease. The diagnosis could be confirmed by finding the parasite in the blood, the cerebrospinal fluid, or post-mortem in the tissues. Tests for antibodies also helped in the diagnosis. Since the incidence of this disease was not known, and the mode of transmission was also in doubt, it was desirable that any case showing some or all of the known symptoms should be investigated with the diagnosis of toxoplasmosis in mind. Every effort should be made to find whether there had been any contact with an infected animal.

NORTH OF ENGLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY

At a meeting of the North of England Obstetrical and Gynaecological Society held in the Jessop Hospital, Sheffield, on October 21, the chair was taken by the president, Mr. S. B. Herd.

Professor A. M. CLAYE described a case in which a sewing needle, which was not of surgical type, had been removed from the abdominal wall fourteen years after he had performed total hysterectomy for multiple fibroids.

Dr. T. SMITH discussed as "an unusual ovarian complication of pregnancy" a case in which an adherent ovarian mass had been removed from the pouch of Douglas. The patient was four months pregnant. On section, decidua-like tissue without demonstrable endometrial tissue was found, and the suggestion was put forward that the mass was a decidual tissue tumour arising from an ovarian endometrioma.

Dr. F. J. MILLYARD described a case of "uterine carcinoma *in situ*." The patient, aged 48, had had irregular uterine haemorrhage for one year and had uterine enlargement corresponding in size with a three-months pregnancy. On hysterectomy a gross endometrial hyperplasia was found which on section showed a non-penetrating carcinoma of the endometrium.

Dr. C. R. MACDONALD gave details of a case of the rare benign haemangioma of the uterus which he had treated by hysterectomy.

Dr. WILLIAM HUNTER discussed the diagnosis and treatment of "double uterus," and confined his remarks to cases in which two separate and distinct uterine cavities had been demonstrated, excluding cases with a rudimentary uterine horn. He had based his studies upon an analysis of a series of 27 cases and a survey of the literature.

Dr. Leslie G. Housden, member of council of the Save the Children Fund and one of its medical advisers, is shortly leaving England to visit the Sudan and British Somaliland on behalf of the Fund. He will survey conditions of child life there in order to see how the Save the Children Fund can best respond to appeals for help which have reached it from the Governor-General of the Sudan, the Colonial Office, and the Governor of British Somaliland.

Correspondence

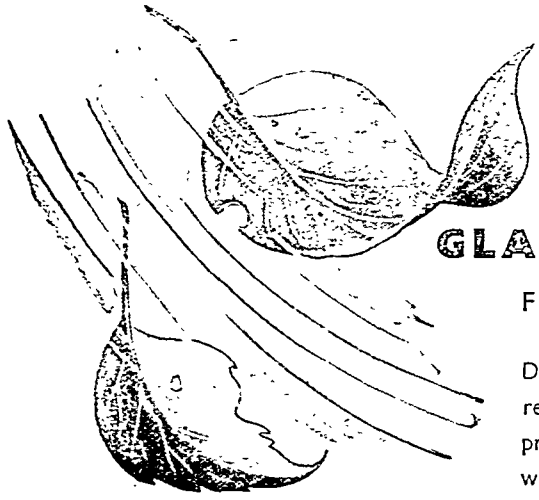
Sunday's Wonder Drug

SIR,—Your leading article on streptomycin in the current issue of the *Journal* led a reporter of the *Sunday Express* to ring me and ask my view upon it. I gave him my opinion in the following words:

> The warning against the present somewhat indiscriminate use of streptomycin is very opportune, even though the general assessment of value of drug is on the pessimistic side. The story of streptomycin illustrates once more the tendency to overstate the range of usefulness, and to understate the toxic or side-effects, of new remedies. Actually, as the article states, the range of useful action is less than penicillin and the degree of undesirable side-effects is greater. The moral is (1) accurate diagnosis of the patient's condition. (2) forbearance in the use of any new drug till its limits are known; (3) careful oversight during its administration.

The reporter thanked me and said this was just what he wanted. But my opinion was not published, as no doubt the Editor considered it spoiled the story he was bent upon telling —I am, etc.,

HORDER.



Virus Diseases in Pregnancy

SIR,—May I use your columns to appeal to medical practitioners to treat me with forbearance and to give me a little help in an inquiry that I am making into the possible effects upon the foetus of certain infectious diseases in the mother during pregnancy?

The position is this. There is, I believe, no doubt whatever that rubella early in pregnancy can cause defects in the child. What we do not know with any pretence to accuracy is the frequency with which the disease, occurring at different stages in pregnancy, will lead to such abnormalities. We can hardly talk of therapeutic abortion as being necessary for a woman who suffers from rubella during the first three months of her pregnancy (and such a step *has* been proposed) unless we know how often the child subsequently born has congenital defects and with what severity. That is not easy to find out. It implies the observation of an attack of rubella in a pregnant woman particularly in the first few weeks of pregnancy before she usually comes under medical observation, and a subsequent study of the child born.

Earlier this year Dr. T. McL. Galloway and I published a few observations of this kind (*Lancet*, 1949, **1**, 299). I am now hoping to extend them with the assistance of the Ministry of National Insurance, and at the same time to include some other infectious diseases the possible effects of which we do not know. The technique I have adopted is as follows. An insured woman in employment may be certified by her general practitioner as being absent from work through an attack of rubella, chicken-pox, mumps, or measles. The local office of the Ministry of National Insurance automatically receives a record of the illness and will make a special note of it whenever it bears one of these diagnoses and relates to a married woman. The same woman may claim maternity benefit for a birth that takes place within 12 months of the beginning of this previously recorded illness. In such circumstances the Ministry of National Insurance has an automatic record of the "double event"—a specified illness occurring at a specified date during (or just before) pregnancy and the date of birth of the child.

When this double event occurs the Ministry will notify me of the occurrence, but to ensure that the practitioner's certificate remains entirely confidential I shall *not* be given the name of the woman concerned. All that I shall know is that such an occurrence has taken place in the practice of one Dr. A. B. The Chief Medical Officer to the Ministry of National Insurance will himself send the name of the patient to Dr. A. B., with an explanation of the circumstances. At the same time I shall write to Dr. A. B. to ask whether one of my medical colleagues may visit him (or her) to discuss the nature of the

GLAXO PRODUCTS

FOR WINTER PRESCRIBING

Detailed below are five Glaxo products of particular relevance at this time of year. One has a specific preventive role; four are nutritional supplements with a notable record of success in winter use.

COLD (anti-catarrhal) DISSOLVED VACCINE Glaxo

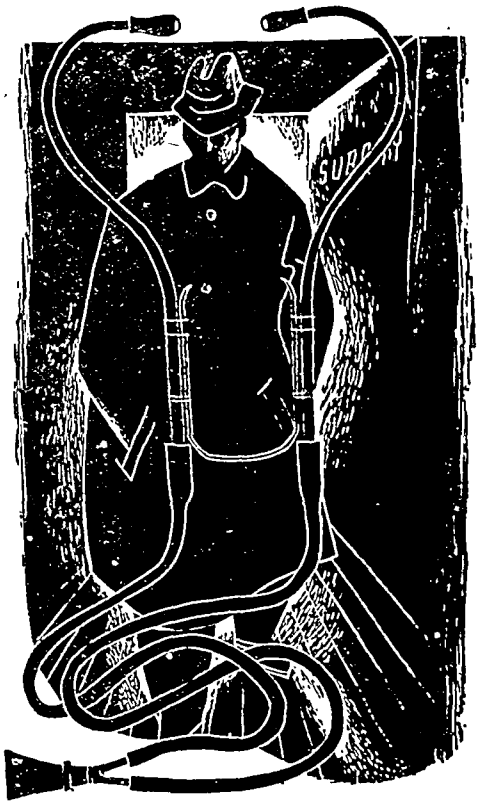
As a prophylactic against the common cold this vaccine can arrest or mitigate symptoms or shorten duration. For subcutaneous injection, each 1 cc. containing in solution the detoxicated antigens of:—

B. pneumoniae (Friedlander)	25 million	*Staphylococcus*	100 million
M. catarrhalis	25 million	*C. coryzae*	25 million
Pneumococcus	150 million	*H. influenzae*	100 million
Streptococcus (respiratory)	150 million		

In 5 cc. and 25 cc. bottles

COLLOIDAL CALCIUM with 'OSTELIN'

Injection treatment of chilblains, urticaria, and certain other allergic conditions. Each 1 cc. contains 0.5 mg. calcium and 5,000 i.u. vitamin D (calciferol) in colloidal solution. For subcutaneous injection.
Ampoules: In Boxes of 6, 12 and 100 x 1 cc. In Bottles of 30 cc.



ADEXOLIN Vitamins A and D concentrate. An important vitamin supplement, for oral administration. The capsules are intended primarily for your adult patients; the liquid is virtually tasteless and most suitable for infants and growing children.
Capsules: In tins of 25 & 100. Liquid: In ½ oz. & 2 oz. bottles.

OSTOCALCIUM Oral protection against chilblains and other peripheral circulatory disturbances. Each peppermint-flavoured Ostocalcium tablet contains 125 mg. of calcium, with 500 i.u. vitamin D (calciferol).
Tablets: In bottles of 50; tins of 100.

OSTOMALT A powerful aid to the growth of healthy tissue and a well-tried general tonic. Combines vitamins A and D, calcium glycerophosphate and orange juice in a rich malt base. Highly concentrated, making *teaspoonful* doses sufficient.
In ½ lb. & 1 lb. jars.

GLAXO LABORATORIES LTD

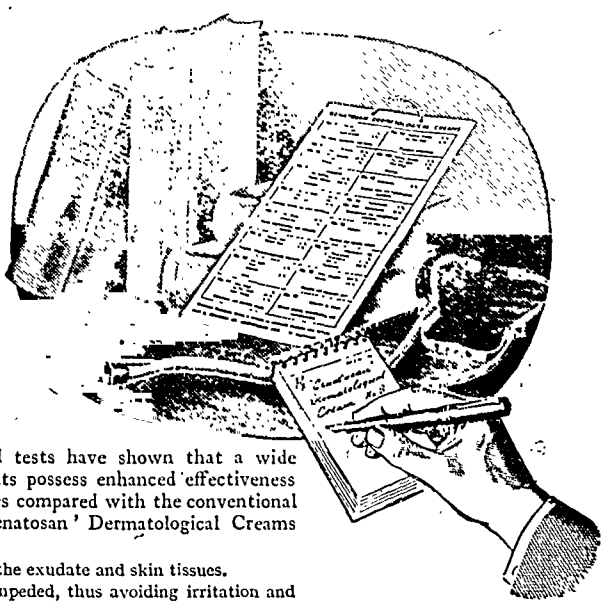
GREENFORD, MIDDLESEX

"the patient who won't fit in...."

The mentally depressed patient who will neither "fit in" with his surroundings nor co-operate in treatment presents a stubborn and increasingly widespread problem in these difficult days. In such a case, a drug is called for that will improve the patient's mental outlook and overcome his inertia. The answer, both in sickness and in convalescence, is provided by the remarkable stimulant effect of

'Tabloid' brand 'Methedrine'

d-N-Methylamphetamine Hydrochloride, 5 mgm. Bottles of 25, 100 and 500



BURROUGHS WELLCOME & CO. *(THE WELLCOME FOUNDATION LTD.)* LONDON

Effective Skin Therapy with

'GENATOSAN'

DERMATOLOGICAL CREAMS

BACTERIOLOGICAL and extensive clinical tests have shown that a wide range of bacteriostatic and fungistatic agents possess enhanced effectiveness in 'Genatosan' water-miscible ointment bases compared with the conventional greasy ointment bases. Advantages of 'Genatosan' Dermatological Creams include the following:—

1. The medicament rapidly diffuses into the exudate and skin tissues.
2. Heat radiation from the skin is unimpeded, thus avoiding irritation and discomfort.
3. The cosmetic texture is not displeasing to the patient due to the vanishing cream base — thus ensuring conscientious use.

Further information and literature available on request to

GENATOSAN LTD

congenital defects, if any. In the first instance the inquiry will be limited to the London and Home Counties area.

Cases of infectious diseases in the pregnant woman are uncommon, and I shall be surprised if I secure, all told, more than a hundred cases in a year. In short, I am unlikely to weigh down any general practitioner with work, but I have all the more reason to endeavour to lay hands on every case I can. I hope the relatively few medical practitioners to whom I shall have to write will listen sympathetically to my plea. Of course I would not say no to any doctor who might care to offer assistance personally by recording cases outside the sphere of employed married women, to whom my scheme is necessarily limited. But my request is not, in fact, for that help but for something very much slighter, yet essential if an important problem is to be solved.—I am, etc.,

A. BRADFORD HILL.

Department of Medical Statistics,
London School of Hygiene and Tropical Medicine,
London, W.C.2.

"Mantoux-conversion"

SIR,—I strongly support Dr. Charles Newman's plea (November 12, p. 1111) for the avoidance of two words, "conversion" and "inversion," for the same process. His criticism of my importation of "inversion" is right; referring frequently to the Scandinavian literature on B.C.G., I had fallen into their usage of the word. I agree with Dr. Newman that etymologically "conversion" is correct and join with him in hoping that "our Scandinavian friends . . . will be willing to drop the term 'Mantoux-inversion.'" I myself shall do so in future.

But a more difficult point arises over a word for a person who undergoes conversion or reversion, and I should welcome advice on this. The Scandinavians use "inverter" and "reverter" (Dr. Konrad Birkhaug, of New York, spells them "-or" in his foreword to my book). Though "reverter" is allowable, is "converter"? The purist would insist that it should be "convert," but this has a religious connotation. Some may even argue that it should be "convertee," but I refuse to assist at the birth of so monstrous a word.—I am, etc.,

K. NEVILLE IRVINE.

Henley-on-Thames.

Modern Trends in Radiology

SIR,—Whatever may be the merits and demerits of mass radiography, Dr. J. F. Brailsford (October 1, p. 724) is to be commended for his courageous attack on the abuse of radiology in general. Apart from the fear of litigation, the main reasons for this abuse are as follows.

First, there is the scientific neo-mediaevalism which believes that an *x*-ray film is bound to "show something." The most flagrant example is the incessant demand for *x*-ray examination following injuries, however slight, to the front of the chest adjacent to the sternum, regardless of the elementary fact that costal cartilage is radio-transparent. Secondly, as has often been said, slavishness to the machine has caused a deterioration in clinical examination and the eclipse of logical thought. Medical teachers continually deplore this state of affairs but seem powerless to remedy it. Thirdly, ambition, pride in craftsmanship, and commercial competition—admirable motives which in other spheres of activity increase the national wealth—in medicine inevitably lead to perpetual expansion out of all proportion to the practical results achieved.

Before the appointed day this country had a flourishing export trade in films. Since that day the supply has been insufficient to meet home needs. The Ministry, instead of using this shortage to bring doctors, auxiliaries, and the public to their senses, stimulated home production and imported films from abroad. Twice within a few weeks I have been urged to lay in a stock of Belgian films. Thus workers have been drawn from the creation of wealth and the balance of trade in films has been reversed to our economic disadvantage, with no gain to our standard of health. I cannot imagine that the Belgians indulge in this extravagance, and from all accounts they are better fed than we are. Their sense of values is evidently superior to ours. It is quite impossible to make the younger generation understand the simple fact that every film expended through carelessness or ignorance or merely for the satisfaction of personal ambitions makes our food dearer and lowers our standard of living.

Even the appeal to self-interest falls on deaf ears. The machine costs money—in labour, replacement, and consumption of materials. Honorary staffs of voluntary hospitals were independent of their hospital's resources. Now all payments come from the same source and the total sum is limited. It stands to reason, therefore, that the more that machines are used instead of brains the more of this sum will be used to pay the machines and the less will be left to pay the brains. We cannot have it both ways.

These things are very, very simple, so simple that I am almost ashamed to mention them. Yet perhaps their simplicity is the reason why they are not understood.—I am, etc.,

FF. ROBERTS.

Cambridge.

SIR,—As radiologist to a provincial hospital group I would like to support Dr. J. S. Gemmill's admirable letter (November 5, p. 1046). Dr. Brailsford's crusading zeal is well known, but there is a vast deal of truth in what he says. Diagnostic radiology must be complementary to clinical medicine. It can never be a substitute for it. The number of cases a doctor refers for an *x*-ray examination is often in inverse proportion to his clinical ability. Requests are constantly being made for elaborate and multiple *x*-ray examinations of several systems without any adequate clinical investigation.

I have been impressed in the last few years by the increasing number of patients—particularly with chest conditions—demanding *x*-ray examinations, not because of disease but because of the fear of disease. Radiology is a very expensive method of investigation and reassurance. The ever-increasing demands made on hospital departments and the flooding out of the department with unnecessary work can only hinder that leisurely and detailed investigation of the case in which radiology can help. For the same reason the all-important consultation with one's clinical colleagues is made so much more difficult. In the last analysis it is the radiologist who alone can appreciate the clinical facts, the help, and, still more, the limitations of his specialty.—I am, etc.,

E. OWEN FOX.

Eastbourne.

SIR,—The material presented in my paper (October 1, p. 724) was not the provoked outburst of an enthusiast but the gleanings from many years of careful observations, applied research, and approved opinions obtained in discussions with eminent clinicians both here and in America. I see no evidence in the criticism to alter the views expressed.

It would have been courteous to your readers, particularly in these days of paper shortage, if the critics had given evidence that they had studied my article and the material in the papers to which I referred, which answered their criticism, before writing their letters. The sole reason for the references was the desire to avoid repetition and save valuable space in your *Journal*. It is particularly noticeable that my critics have taken certain passages from their context, put their own interpretations, not mine, on their significance, and then called it nonsense—even I agree with them. Thus, in my article I stated that "there would be fewer errors in interpretation of radiographs if radiology was always preceded by a *sound* clinical examination," and Dr. Peter Kerley (October 15, p. 870) states, "It is not misinterpreting Dr. Brailsford to summarize his views on the diagnosis of tuberculosis and carcinoma as follows—wait until the patient has a big haemoptysis or a palpable tumour." Would it not be reasonable to point out that, if this is the standard of his clinical examination, what he does not know about clinical medicine is practically all there is to be known?

It is amazing to me to see that men engaged in these mass examinations fail to appreciate the mental and physical pain which their activities produce. I need produce no other facts or figures to condemn mass radiology than those provided by Dr. Peter Kerley. He states that three and a half million people were examined by mass radiography and that "as a result of the initial examination 13,401 were found to be suffering from active tuberculosis necessitating treatment. Samples of these patients compared with samples of patients reporting with symptoms to chest clinics have shown that those detected by mass radiography require from six to seven months' treatment before returning to work, as against 18 months to two years

required by those reporting to chest clinics." Since we have been told that most of the cases detected by mass radiography had no signs or symptoms, and since by far the greater number of these cases have had tuberculosis and must have recovered from it without having had any treatment, was it necessary to keep them in sanatoria for six months before sending them back to work? (We have 5,669 beds in sanatoria empty because of the shortage of nurses.) On the other hand, of the cases referred for radiography by the general practitioner because of signs and symptoms, many show so-called minimal lesions, but even with prompt sanatorium treatment progression continues for a time, and few would be considered by the tuberculosis officer to be fit for work in six months' time—some die though every expedient is used.

Dr. Kerley's second statement is open to even more serious criticism. He states, "A still larger group of individuals with minimal tuberculous lesions or lesions of doubtful activity detected by mass radiography have been kept under observation while at work." Why? Perhaps the best explanation can be obtained from the cases cited in the Prophit Tuberculosis Survey.[1] Take, for example, Case 108:

"English nurse. *X* ray normal in September, 1938. In April, 1942, doubtful shadow below right clavicle—in September, undoubted lesion. No symptoms, no clinical signs of activity. Remained on duty. January, 1943, definite spread and probable commencing cavitation. Feeling quite fit; E.S.R. 10. In March, 1943, further spread, and definite small cavity. The nurse still had no symptoms, and was still on duty. The following month, *while on holiday* (my italics), she complained of increasing malaise, persistent cough and sputum, and huskiness. In July, 1943, the infraclavicular cavity was larger and well defined and sputum was found to be T.B.+. A.P. was then induced"

In the face of the radiographic evidence of progressive disease, why was the nurse kept on duty? We must believe either that the statement that she had no symptoms was false, that the clinical examination was poor, or that the holiday caused the symptoms. Is it not possible that she tried to hide the symptoms and that the medical officer, short of nurses, too readily accepted the statement? The detection of the early lesion by radiography did not secure her treatment: this she got, in spite of radiographic evidence of progressive disease, only after she had developed signs of a severity which could not have escaped the clinical acumen described by Dr. Kerley.

Dr. S. Cochrane Shanks and Dr. Peter Kerley are advisers to the Ministry of Health on radiography, and neither they nor their assistants can be said to be free from vested interests. They are obviously angry that I should suggest that in these days of bankruptcy, when we have 5,669 empty beds, their service, which merely finds a few more cases they have not the means to treat, should be abandoned and the money devoted to those purposes which raise the resistance to the disease. From their concerted statements—"It is deplorable that such nonsense should have been given space in a scientific journal" (October 15, p. 870)—they indicate clearly that if they had the power they would prohibit it. Many distinguished clinicians have expressed entire approval of my constructive criticism.

Material from most radiographic departments could be obtained which proves the lack of judgment, skill, and knowledge on the part of certain doctors in carrying out on patients the procedures the significance of which I suggested students might learn by performing on each other. Is it nonsense to say to such people, "You have it done to yourself by someone as incompetent as yourself and see if you would then think it justifiable"?

Dr. F. Kellerman (October 15, p. 870) need have no fear for the reputation of British medicine in my hands. Constructive criticism of trends is not condemnation of the whole. The many honours bestowed upon me before and during my extensive tour of the U.S.A. were in acknowledgment of my contributions to the literature, and I can assure him that I have every reason to know that I left in every State an enhanced opinion of British medicine.

Edgbaston, Birmingham. JAMES F. BRAILSFORD.

Use and Abuse of Vitamins

SIR,—In his article on the use and abuse of vitamins (November 5, p. 1036) it is noteworthy that Professor L. S. P. Davidson never refers to the human factor. He is satisfied that the general practitioner, if adequately trained in the science of nutrition, is the proper person to give advice to the family on how to eat, when to eat, and what to eat. Is he as well satisfied that the family will accept the advice?

Every doctor in touch with the people knows that they will eat what they like when they can get it, and will not eat what they do not like unless they are hungry and can obtain nothing else. It is obvious that if the populace was sufficiently regimented to conform to the instructions of the dietitian (and how these dietitians can disagree) there would be no need of vitamin preparations except in infrequent cases.

I know what my patients should eat. I advise, but I am well aware of what they really do eat and what they will not eat. They are not cranks, merely a cross-section of our population. Taking these people as we find them, desiring to help them, and knowing that health propaganda, particularly in the field of dietetics, is likely to be tedious and show little effect in our lifetime, it is found necessary to prescribe vitamin preparations much more frequently than would appear to be necessary from Professor Davidson's article.—I am, etc.,

Hexham, Northumberland. RICHARD BELL.

Teaching of Physiology

SIR,—It is unfortunate that Dr. M. Beddow Bayly (November 5, p. 1048), whether wilfully or unconsciously, completely missed the point of Professor D. H. Smyth's letter (October 8, p. 813) on this subject. This was a plea that the medical profession as a whole should help to guide public opinion so that at least some fraction of the hundreds of thousands of cats and dogs destroyed annually in this country should be made available for physiological teaching and research, on which, ultimately, all advances in medicine depend. Instead, Dr. Bayly concentrated on the word "restrictions," referring to them as "undesirable restrictions," and proceeded to fill a column in asking why they were undesirable. Professor Smyth had neither suggested nor implied such an idea. In common with all physiologists in this country, he knows that the restrictions imposed by the Home Office are highly desirable, for they afford the protection of the law against interference from the antivivisectionists. They offer no hindrance to research, since little of physiological value could be obtained from experiments on animals in acute emotional distress.

It is possible that Dr. Bayly is himself a member of an antivivisection society—his illogicality is typical of their pronouncements. If I misjudge him, and his misreading of Professor Smyth's letter was not deliberate, I offer my apologies. The whole question of the supply of cats and dogs for research is so acute, and of such importance to the future of medicine in this country, that attempts to draw attention from it must not be allowed.—I am, etc.,

London, W.C.1. M. GRACE EGGLETON.

Reform in Medical Education

SIR,—The article on "Reform in Medical Education" by Professor W. Melville Arnott (September 3, p. 497) is a notable contribution to the literature on this subject. It should prove most useful to those who are responsible for framing curricula in numerous medical schools. Where so much is excellent, one hesitates to criticize, but there appear to me to be three points which call for comment.

(1) If one infers correctly, the author is of the opinion that physical examination of the chest is a clinical method inferior to that of examination by radiography, and that the only purpose of such method is to provide practice "against the time when radiology is not available." Surely, however, there is to be obtained from physical examination of the chest much information which may not be revealed by even the very best

radiograph. Furthermore, there are many points concerning the functional aspects of the thorax about which the radiograph will tell us nothing. Professor Melville Arnott may look upon these points as axiomatic, and possibly the statement in the *Journal* does not represent the full text of his address to the East Yorkshire Branch of the B.M.A.

(2) "Mathematics to a higher standard, including elementary statistical methods and an introduction to the calculus . . . should be an essential requirement for admission to a medical school." There is no doubt that such knowledge is most useful to a medical student, but if the possession of it were made a condition of entry, one feels, from long experience of medical students, that such insistence would preclude the admission of many to the medical faculty.

It might here be mentioned that Professor E. C. Dodds, in his article in the same issue of the *Journal* (p. 505), states, "I have been impressed with the curious allergic objection that they (medical students) have to any form of mathematics," and, further, he says, "It is possible to explain to students the phenomena of physical and colloid chemistry without recourse to higher mathematics." One has noticed over a period of years that not a few students who do very well in mathematics do not do well in other subjects of a biological nature requiring skill in the fundamental disciplines of clinical examination. It was shown in a paper a few years ago that too great insistence on mathematical ability would have deprived a number of Australian hospitals of some first-class clinicians. A paper by D. H. Smyth, quoted in the article, bears out the fact that there is room in the medical profession for men and women possessing very diverse aptitude.

(3) As Professor Melville Arnott says, the selection of students is a most controversial question. Experience over a number of years with the interview, however, convinces one that this procedure has very definite limitations. It has been said very truly that it is only by living with people that one comes to know them well. If all intending medical students who were physically fit were required to undergo a year of national service, with a proportion of time given over to scholastic work as in a Service training college, it would be possible to obtain from their instructors the information that university authorities are seeking.—I am, etc.,

Brisbane. E. S. MEYERS.

Treatment of Ringworm of the Scalp

SIR,—There are certain statements in the letter by Drs. J. Martin Beare and Ivan H. McCaw (October 8, p. 815) which call for further comment. The literature by no means confirms their contention that 25% of *M. audouini* infections of the scalp undergo spontaneous cure in less than six months. In fact there are countless reports, such as that of Lewis[1] and Lewis and Hopper,[2] in which such cases have been treated by local methods for long periods of time without any response whatever. Even in series such as that of Livingood and Pillsbury,[3] in which some 33% of "spontaneous" cures were claimed despite the fact that local treatment was applied the whole time, it took anything up to two years for the cases to become finally clear. It is evident, therefore, that this factor is of little or no importance when evaluating any method of treatment which will cure this condition in an average time of three months or less.

At this point it may be emphasized that the desirability of rendering these cases non-infective as soon as possible precludes the possibility of using untreated cases as controls. While the use of a toothbrush in applying the ointment to the scalp may be regarded as a useful "additional mechanical factor," as Drs. R. T. Brain and H. Haber and Mr. J. W. Hadgraft point out in their paper (September 17, p. 626), it has never been suggested that it is anything more than this, and it is difficult to imagine how it could ever approach in efficiency manual epilation with forceps by a skilled operator as Drs. Beare and McCaw suggest. In any case, except for academic reasons, surely it is quite immaterial whether the toothbrush assists the action of the local application or not. The fact which is of real importance, as the previous paper by Brain and his colleagues[4] and the preliminary communication by Drs. A. J. E. Barlow, F. W. Chattaway, and C. S. Whewell (October 15, p. 875) shows, is that this method of treatment is capable of curing some 75% of cases of *M. audouini* infection in an average time of 8–9 weeks without its being necessary to resort to manual epilation with forceps or any other procedure which cannot be carried out by the parent at home This last point is, I think, of particular importance.

Although Drs. Beare and McCaw had four cases of contact dermatitis out of 14 cases in which salicylanilide in carbowax was used, they do not state the concentration of the fungicide or whether the preparation contained any other substances which may have caused sensitization. It should also be pointed out that both Schwartz and his colleagues[5] and Kinnear and Rogers[6] treated a considerable number of cases with salicylanilide not exceeding 5%, and no cases of contact dermatitis were reported. Irritation due to mechanical friction should be distinguished from true sensitization dermatitis.

While it was admitted by Brain and his colleagues[4] that *x*-ray epilation still afforded the quickest and most certain method of cure, it should be remembered that at many specialized centres practising this form of therapy there is a wait of sometimes three to four months before treatment can be commenced. Add to this the four or six weeks required for cure and the total time is some three to four months, which is four to eight weeks longer than the time taken to cure 75% by effective local therapy. In almost every case which yields to local treatment a distinct reduction in the number of infected hairs as seen under Wood's light seems to occur within eight weeks, and usually much sooner, thus enabling one to sort out at this stage with a fair degree of certainty those which will probably require *x*-ray epilation. This can then be arranged. It will be seen, therefore, that even the 25% of failures can then be assured of a probable cure in a total time of five to six months.

It might be as well at this point to summarize the main disadvantages of *x*-ray epilation[7]: (1) Permanent alopecia is extremely unlikely in the most expert hands, but always remains a possibility, especially with less expert operators. Shanks[8] instances nine cases in 2,400 epilations. (2) Apparatus and expert radiotherapists are not available everywhere. (3) *X*-rays are unsuitable for very young children and quite often necessitate an anaesthetic with its negligible but nevertheless ever-present risk. (4) Hair is longer regrowing than after local therapy, which is a particular disadvantage in the case of girls.

I would suggest, therefore, that the method of treatment outlined by Brain and his colleagues,[4] while suitable only where facilities exist for examination under Wood's light and, preferably, culture of the organism, should be used in preference to *x*-ray epilation under the following circumstances: (1) in all cases of pre-school age; (2) where facilities for *x*-ray epilation are not available within a very short time, and especially during epidemics; (3) in all cases of infection with the animal microsporon—e.g., *M. felineum* or *M. lanosum*.—I am, etc.,

Treatment of Erysipeloid with Penicillin

SIR,—I am prompted by Dr. R. A. Bush's medical memorandum concerning his case of erysipeloid of Rosenbach (October 29, p. 964) to let you know of my experience. During the past year I have seen four cases. The diagnosis was made on clinical grounds; a painful, slowly spreading erythema was present and there was a history of contact with raw meat or fish. In all cases the hand was the site of the lesion, which had been present for roughly one week before medical attention was sought.

As some cases are said to respond to sulphonamides[1] a course of sulphamezathine was started, but it was evident that the area involved was extending, and after three days the drug was stopped and replaced by penicillin intramuscularly. It was

given in doses of 500.000 units in aqueous solution at 24-hour intervals. The patients continued at their work and no local treatment was administered. The response in all cases was dramatic; 24 hours after the first injection the colour was fading. Twenty-four hours after the second injection the skin appeared normal, but some pain was present on movement. A third injection cleared this, and no further treatment was given.

One of the patients defaulted after the second injection, but the condition resumed activity after two days and the patient attended again. It would appear that in addition to the skin clearing one must be sure that movement is painless before pronouncing the patient cured.—I am, etc.,

Huddersfield. N. V. SAPIER.

Hypnosis in Treatment

SIR,—Dr. K. M. Hay (October 15, p. 874) remains far from being reassured of the possible dangers of hypnosis to the personality. I have tried to allay his fears and suspicions in my last letter (October 1, p. 756) by reporting that in the light of present knowledge no evidence of personality danger exists during hypnosis as demonstrated by the Rorschach test. Dr. Hay dismisses such evidence as invalid because he doubts that the Rorschach test is anything more than a modified ink-blot test and can be nothing more than a rough measure of the personality biased by one psychological school or another.

Agreed that the Rorschach test is as yet an imperfect measure of the personality, yet it remains a universally recognized test of personality and is considered by many as the most efficient of such tests in the psychological armamentarium. It is certainly a more accurate and scientific investigation of the personality than that which might be revealed by any inquiry conducted by general practitioners, religious leaders, and philosophers as was advocated by Dr. Hay in his earlier letter (September 17, p. 653).—I am, etc.,

London, W.14. NEVILLE MURRAY.

Infantile Enteritis

SIR,—I have read with interest your leading article (July 15, p. 141) on the aetiology of infantile enteritis and the paper in the same issue (p. 117) by Drs. Joan Taylor, B. W. Powell, and Joyce Wright describing an investigation of the aetiology and treatment of this condition. From the statements in the *Journal* it does not appear likely that you have read my papers.[1,2] These investigations I carried out on infantile diarrhoeas occurring in infants in nurseries for the newborn in Ontario. The epidemics, 10 in number, occurred from December, 1940, to September, 1943.

At that time, during the bacteriological investigations of faeces and other specimens obtained from sick infants and fatal cases, I was impressed with the large numbers of *Bact. coli* in these sick infants. Many of these colon organisms showed distinct zones of haemolysis around the colonies on sheep-blood agar plates but failed to show any appreciable haemolytic titre against sheep or rabbit blood cells in the test-tube.

It is quite possible that the toxin liberated by many colon organisms can produce the characteristic symptoms in infants if they are suddenly swamped with large numbers of viable, toxin-producing organisms in their feeds. Histamine may be produced and may be one of the factors causing the severity of the symptoms. I suggest five reasons for suspecting the *Bact. coli* and their ability to produce symptoms in these infants. (1) Abundance of these organisms in sick infants and fatal cases. (2) Production of scours in calves due to colon organisms; Theobald Smith reports that calves which did not receive the colostrum milk were more often attacked. (3) Presence of lysozyme in mothers' milk and not in cows' milk. (4) *Bact. coli* bacteriophage absent in the intestinal tract of the newborn infant. (5) Production of toxins from colon organisms and their ability to produce diarrhoea, vomiting, and even death in cats.

As I have stated, the possibility of a virus has not been excluded. Light and Hodes were able to produce diarrhoea in Guernsey calves from filtrates of the faeces taken from affected infants. I am not aware that this finding has been confirmed by other workers. All these investigations should once again stress the importance of breast-feeding. It was noted in these epidemics that premature infants were the first to become ill and were the first to die. It was not until a normal infant became ill that the epidemic was recognized.

I am now practising in a mission hospital in South China, and here at least 95% of the infants are breast-fed. We do not have these epidemics in the nursery. We do not have feeds of cows' milk lying around to become contaminated with *Bact. coli*. The fermentative reactions which occur in the intestine of the breast-fed infant keep the numbers of colon organisms greatly reduced, until the infant can deal with them and create an immunity against the toxins produced by them, or whatever the process is that enables the infant to accustom itself to them.—I am, etc.,

Kongmoon, South China. WALLACE B. MCCLURE.

Dosage of Penicillin

SIR,—It seems to me that during the last few years the dosage of penicillin recommended in the treatment of various maladies has steadily risen. When we first received supplies of penicillin for trial we were told that after exhaustive research it had been found that 15,000 units three-hourly or a total of 120,000 units in 24 hours maintained an effective blood level.

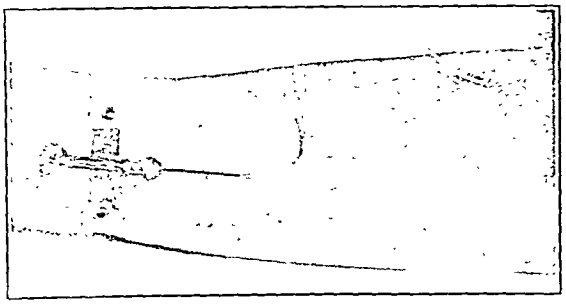
In the article by Mr W. M. Mollison entitled "The Acute Ear" (October 22, p. 923) there is recommended a dosage of 500,000 units of watery solution twice daily—i.e., a daily total of 1,000,000 units—this in spite of the fact that the drug is now provided in a much more pure state.

Has this dosage been arrived at by research in a bacteriological laboratory or is it because of a loss of faith in the power of the drug? Is it a result of clinical experience, or is it simply because penicillin is now so much cheaper that it can be wasted? In all humility I ask, Is this dosage really necessary? Or is it just as ridiculous and wasteful as pushing large quantities of vitamins into a patient who is already getting enough from his diet?—I am, etc.,

Witney, Oxon. L. G. LE CLERCQ.

Buccal Ulcers Caused by Isoprenaline

SIR,—We have recently had in the Middlesex Hospital, under the care of Dr. G. E. S. Ward, three patients suffering from asthma who presented an unusual and trivial, but to them distressing and to us inconvenient, complication. They obtained good relief from attacks by sucking a tablet or half a tablet (10–20 mg.) of isoprenaline under the tongue. The first patient complained of "sores" in her mouth which looked like aphthous ulcers and were treated accordingly. She had been discharged before similar lesions occurring in two further patients drew our attention to the possibility that they were caused by isoprenaline. That this was so was readily confirmed. Two brands of isoprenaline ("neo-epinine" and "neodrenal") were tried, and both caused ulceration.



Neither of these patients showed sufficient skill or understanding to obtain comparable relief from hand-operated spray inhalers, so we sought for a way to avoid this unpleasant side-effect. It seemed reasonable to suppose that the buccal mucosa was in some way damaged by prolonged contact with the vaso-constrictor drug when concentrated in a tablet, so we tried powdering the tablet in a small amount of liquid (rather less than half a teaspoonful of lemon syrup was used, but this is only arbitrary) before giving it to the patient to suck. This had the desired effect, and both patients were able to use the tablets satisfactorily with no further trouble.

It is felt that this complication and the simple manœuvre by which it is avoided are worth reporting, because isoprenaline is valuable in the relief of asthmatic attacks, especially so in those patients who are unable to master the (albeit elementary) technique of using and looking after a hand-spray inhaler.—I am, etc.,

London, W.1. MORAN CAMPBELL.

Heparin Administration by Polythene Tubing

SIR,—I was very interested by Dr. W. A. L. MacFadyen's note (October 22, p. 925) on the use of polythene tubing and a diaphragm adaptor for the intravenous administration of heparin. I have for some time been giving heparin by a similar method, but have used the Robertshaw modification of the Gordh adaptor. This adaptor is similar to that described by Dr. MacFadyen but is provided with a wide metal flange which facilitates attachment to the arm. Although this adaptor is supplied with a rubber strap for fixing it to the arm, it is in practice much better to attach it with a length of elastic adhesive strapping as shown in the accompanying photograph.

Robertshaw-Gordh adaptor with 14 s.w.g. needle and fine polythene tubing. After sterile dressings have been applied over the diaphragm and the puncture wound, the whole apparatus is covered with a soft bandage.

A further advantage of this apparatus is that the diaphragm is set at an angle to the needle, which facilitates injection.

This needle adaptor is supplied by A. L. Hawkins and Co., Ltd., 15, New Cavendish Street, London, W.1, and it has been in use in a number of the wards of St. Bartholomew's Hospital. I can certainly vouch for the simplicity of the apparatus, which has completely revolutionized heparin treatment. Whereas the ordinary Gordh needle cannot be used in the antecubital fossa, the polythene tubing can be readily inserted here and pushed up the vein for an inch or two above the elbow (this is often especially useful in those patients who, having no suitable forearm veins, could not previously be treated easily with the ordinary diaphragm needle).

Finally, I would like to emphasize that many patients are up and about throughout the period of treatment, the polythene tube remaining in the same vein for four or five days, and sometimes for as long as 10 days.—I am, etc.,

Radlett, Herts. R. S. MURLEY.

Carbachol for Migraine

SIR,—Ophthalmologists will be grateful that such an authority as Sir John Parsons thought it necessary to comment (October 29, p. 980) on the article by Dr. G. S. Graveson (October 15, p. 838). The majority will agree with his remark that Dr. Graveson's article is liable to misrepresentation and may cause suffering to migraine subjects.

I have been particularly interested in this condition for many years, and I have never found a case of permanent homonymous field defect due to migraine. I do not find that the typical migraine syndrome has the scintillating scotomata as a most frequent sign. I consider the bad headache, sickness, photophobia, and the wish of sufferers to rest in a darkened room are most symptomatic. I am acquainted with the theories of migraine here and abroad, but must say that I have not met many cases of aphasia, tingling, and numbness of fingers and tongue, as described. I have tried to watch the fundal condition in some patients during an attack, and admit my complete inability to see any change in the retinal vessels.

However, my whole ambition in writing this letter is to stress that, whatever theories, syndromes, and ideas we would like to postulate, our great mission as physicians is to bring relief to the unfortunate victims of this or any other condition, and I believe we have a specific for migraine in carbachol. Carbamylcholine chloride is a similar substance to acetylcholine. It is, I believe, resistant to cholinesterase, and is a parasympathetic nervous stimulant and produces peripheral dilatation of the blood vessels. If vascular spasm is the cause, carbachol may counteract it.

Long before the war I used a similar substance, though an inferior one, the German "doryl" (an English preparation was named "moryl"). In an article appearing in this *Journal* in 1945 (May 12, p. 663) Dr. A. K. James gave facts and figures of his treatment of migraine with carbachol. I had prepared a series of cases to report in the *Journal* of my success with "moryl," and I went on to investigate carbachol, and since then I have never failed in curing a migraine attack either temporarily or permanently by the use of this preparation. In fact, I am now so sure of its activity that in bad headaches and conditions simulating migraine where one suspects the history given by a patient I give or advise carbachol, and if there is no immediate improvement I feel the condition has nothing to do with migraine.—I am, etc.,

Walton-on-Thames, Surrey. J. H. MELLOTTE.

New Mechanism of Vitamin Deprivation

SIR,—Under this title Professor A. C. Frazer published an article in your journal (October 1, p. 731). His considerations cover a very wide field—the causes of deficiencies of fat- and water-soluble vitamins, some of which practically have nothing in common but the name vitamin. Several of his statements as well as his main claim to have discovered a new mechanism causing vitamin deficiencies require comment. His conclusions are based on some features of deficiencies of vitamins of the B group—riboflavin, nicotinamide, pyridoxin, and folic acid—as observed in sprue. My comments are as follows.

1. Professor Frazer states that the effect of antibacterial agents on vitamin deficiencies is unknown. This is not so. Considerable reduction of urinary output by man of aneurin[1] and of nicotinamide methochloride[2] has been observed after oral administration of "sterilizing" sulphonamides to humans, some of which were pellagrins. Moreover, cases of nicotinamide deficiencies have been reported after oral application of succinyl sulphathiazole,[3] sulphadiazine, and penicillin.[4]

2. Professor Frazer states that all these vitamins mentioned by him are essential growth factors for bacteria, particularly those which are known to be present in the upper part of the small intestine in sprue. He does not give details of the types found under these conditions. If, however, *Bact. coli*, which are the main producers of nicotinamide in the human intestines under normal conditions, are amongst these bacteria this statement is incorrect, since *Bact. coli* can easily grow without any of these vitamins.[5]
